Xu L, Gebhart GF. Characterization of mouse lumbar splanchnic and pelvic nerve urinary bladder mechanosensory afferents. J Neurophysiol 99: 244–253, 2008. First published November 14, 2007; doi:10.1152/jn.01049.2007. Sensory information from the urinary bladder is conveyed via lumbar splanchnic (LSN) and sacral pelvic (PN) nerves to the spinal cord. In the present report we compared the mechanosensitive properties of single afferent fibers in these two pathways using an in vitro mouse bladder preparation. Mechanosensitive primary afferents were recorded from the LSN or PN and distinguished based on their response to receptive field stimulation with different mechanical stimuli: probing (160 mg to 2 g), stretch (1–25 g), and stroking of the urothelium (10–1,000 mg). Four different classes of afferent were recorded from the LSN and PN: serosal, muscular, muscular/urothelial, and urothelial. The LSN contained principally serosal and muscular afferents (97% of the total sample), whereas all four afferent classes of afferent were present in the PN (63% of which were muscular afferents). In addition, the respective proportions and receptive field distributions differed between the two pathways. Both low- and high-threshold stretch-sensitive muscular afferents were present in both pathways, and muscular afferents in the PN were shown to sensitize after exposure to an inflammatory soup cocktail. The LSN and PN pathways contain different populations of mechanosensitive afferents capable of detecting a range of mechanical stimuli and individually tuned to detect the type, magnitude, and duration of the stimulus. This knowledge broadens our understanding of the potential roles these two pathways play in conveying mechanical information from the bladder to the spinal cord.

INTRODUCTION

Sensory information from the urinary bladder is conveyed via lumbar splanchnic (LSN) and sacral pelvic (PN) nerves to the spinal cord. Mechanosensitivity of bladder afferents underlies in part the pain and discomfort experienced by patients with interstitial cystitis/painful bladder syndrome and other bladder disorders, yet the afferent pathways and constituent afferent fibers that contribute to bladder sensations are incompletely understood. Peripheral terminals of sensory neurons innervating the bladder are equipped to detect a variety of mechanical stimuli, including distension and circumferential stretch of the organ. The mechanosensitivity of bladder afferents in the mouse (Daly et al. 2007; Rong et al. 2002), rat (Mitsui et al. 2001; Moss et al. 1997; Sengupta and Gebhart 1994; Shea et al. 2000), cat (Bahn et al. 1987; Floyd et al. 1976; Häbler et al. 1990, 1993), and guinea pig (Zagorodnyuk et al. 2006) has been studied previously, but the principal focus of study has been the PN.

It has long been appreciated clinically that the two nerves innervating an internal organ have different functions, but this has not been systematically investigated. Nonhuman animal studies have generally used nerve transection with subsequent study of changes in bladder reflexes (e.g., micturition). Conclusions based on such studies are not all in agreement with respect to nerve function or straightforward (see DISCUSSION). More recently, examination of sensory neurons (nerve transection affects both afferent and efferent axons), either afferent fibers or their cell bodies, has provided evidence that the different pathways of sensory innervation of an organ significantly differ with respect to both chemical and mechanical sensitivities (e.g., Brierley et al. 2004; Dang et al. 2005a,b; Sugiura et al. 2005). We recently compared the mechanosensitivity of LSN and PN afferent fibers innervating the mouse colon and noted several important differences (Brierley et al. 2004) between the two pathways, which in conjunction with studies in knockout mice (e.g., Daly et al. 2007; Jones et al. 2005, 2007; Page et al. 2005) could inform development of therapeutic strategies targeting selected molecules and pathways important to visceral disorders.

The availability of knockout mice provides the unique opportunity to examine the role of relevant molecular targets in organ mechanosensitivity and their contributions to visceral hypersensitivity such as characterizes interstitial cystitis/painful bladder syndrome. As a first step to this end, we compared the mechanosensitive properties of single afferent fibers in the two pathways innervating the mouse urinary bladder (i.e., LSN and PN afferents) using an in vitro mouse bladder preparation. We also examined the ability of an inflammatory soup (Handwerker and Reeh 1991; Jones et al. 2005) to sensitize responses of stretch/tension-sensitive fibers to subsequent mechanical stimuli.

METHODS

Male C57BL/6 mice (20–30 g; Taconic Farms, Germantown, NY) were used throughout. All experiments were reviewed and approved by the Institutional Animal Care Use Committee of the University of Iowa.

In vitro preparation and recording of mouse bladder afferents

Mice were killed by CO2 inhalation. The bladder with either the PN or LSN and associated neurovascular bundle was isolated and transferred to ice-cold Krebs solution bubbled with carbogen (95% O2-5% CO2).

The costs of publication of this article were defrayed in part by the payment of page charges. The article must therefore be hereby marked “advertisement” in accordance with 18 U.S.C. Section 1734 solely to indicate this fact.
were present. Further, a clear distinction of action potentials was made using the Spike2 waveform function. If more than two units were present in a nerve filament, the filament was divided into two or more clearly discriminable units. The amplified signal was also used for off-line audio monitoring.

The preparation was allowed to rest for 60 min before recording. The preparation was stimulated by mechanical or chemical means. The bladder stretch was achieved using a hook made from a bent dissection pin that was attached to the tissue adjacent to the receptive field for 1 min. Bladder stretch was achieved using a hook made from a bent dissection pin that was attached to the tissue adjacent to the receptive field for 1 min. Stimulation with a hook made from a bent dissection pin was considered the most effective mechanical stimulus. A mildly acidic inflammatory soup (IS) or vehicle was applied directly to the receptive field. The horizontal lines beneath A and B indicate the onset and termination of stretch (20 s) or von Frey probing (1 g, 3 s) stimuli. Stroking of the urothelium was indicated by dots below the respective records.

Characterization of bladder afferents

the bladder measured in 12 mice was 6.1 (range 5.8–6.5). The IS was prepared in aliquots of 20 μl by combining bradykinin, serotonin, and histamine dissolved in distilled water with prostaglandin E2 dissolved in dimethylsulfoxide, frozen, and stored at −20°C. On the day of an experiment, an aliquot was diluted to final concentration (5 μM for all mediators) in acidified (6.0) Krebs solution.

Data analysis

Data are plotted throughout as means ± SE. Two-way ANOVAs or repeated-measures multiway ANOVAs were performed as appropriate using Prism 5 (GraphPad Software, San Diego, CA). Tukey or Bonferroni-corrected post hoc tests were performed as appropriate when F values for main effects were significant. Differences were considered significant when P ≤ 0.05.

Adaptation profiles to probing were calculated as the mean number of spikes per 100-ms bin over the entire 3 s of the probe stimulus. Adaptation profiles to stretch were calculated as the mean number of spikes per 500-ms bin over the entire 20 s of stretch. Slopes were derived from regression analyses performed on stimulus–response functions and adaptation data to compare the gain and rates, respectively, of afferent fiber responses. Extrapolations of threshold values for stimulation based on a linear regression analysis of stimulus–response functions were determined only for muscular fiber responses to stretch. To compare the sensitivity of splanchnic and pelvic afferents to von Frey probing, the percentage of afferent fibers that responded to each probe force was calculated based on the total number of fibers of each type (“percentage responding”) and evaluated by χ² analysis (Prism 5).

RESULTS

Basic mechanosensory and topographical properties

All fiber types were responsive to perpendicular von Frey probing. However, their receptive field location and response, or lack of response, to mechanical stimuli (i.e., von Frey probing, urothelial stroking, and muscle stretch) distinguished four types of mechanosensitive fibers in the LSN and PN pathways innervating the mouse urinary bladder.

LSN BLADDER AFFERENTS. Three types of LSN fibers could be distinguished based on their responses to mechanical stimuli (Fig. 1A): muscular, muscular/urothelial, and serosal. Muscular afferents (20 of 67 LSN fibers studied) had receptive fields in the bladder wall that were optimally activated by probing and stretch, but were not responsive to fine urothelial stroking (Fig. 1Ai). In response to graded intensities of stretch, muscular afferents typically responded with an excitation that typically adapted during the stimulus, particularly at the greater intensities of stretch tested. Muscular afferents also responded to probing of the urothelium at greater stimulus intensities (500–1,000 mg; data not shown), which we observed to distort the underlying muscle layers. We found no LSN receptive endings sensitive only to stroking of their receptive fields with a 10-mg von Frey filament, but did identify a small proportion of LSN afferent fibers (3% of the sample; 2 of 67 fibers) that responded to both urothelial stroking (10-mg von Frey filament) and graded stretch of the bladder (Fig. 1Aii), which we designated muscular/urothelial. Serosal afferents (45 of 67 fibers studied) had receptive fields located in the bladder wall that were reproducibly activated in a graded fashion only by blunt probing and did not respond either to bladder stretch or fine urothelial stroking with a 10-mg von Frey filament (Fig. 1Aiii). Thus serosal afferents were the most abundant type of mechanosensitive fiber recorded in the LSN; afferent fibers that responded to stretch (muscular and muscular/urothelial) constituted the remainder of the sample (Fig. 2A, bottom). Virtually all LSN afferents possessed a single, small (typically ≤0.5 mm) punctate receptive field from which responses could be most readily evoked; their receptive fields tended to be clustered at the base of the bladder (Fig. 2A, top). Afferents recorded from the LSN were commonly silent at rest. How-
ever, some afferents in this pathway (20%) had low rates of spontaneous activity (≤0.5/s), but no formal analysis of spontaneous activity was performed.

**PN Bladder Afferents.** Four types of PN fibers could be distinguished based on their responses to mechanical stimuli (Fig. 1B): muscular, urothelial, muscular/urothelial, and serosal. As with LSN afferents, all PN afferents responded in a graded manner to blunt von Frey probing of their receptive fields and were distinguished by their sensitivity to fine urothelial stroking and bladder stretch. PN muscular afferents (49 of 78 PN fibers studied) responded to stretch but not fine stroking (Fig. 1Bi), urothelial afferents (9% of the sample; 7 of 78 fibers) responded to fine stroking but not stretch (Fig. 1Bii), muscular/urothelial PN fibers (14% of the sample; 11 of 78 fibers) responded to both urothelial stroking (10-mg von Frey filament) and to graded intensities of bladder stretch (Fig. 1Biii), and serosal afferents (also 14% of the sample) responded only to probing of their receptive field (Fig. 1Biv) and not to any other mechanical stimulus. In contrast to LSN afferent fibers, muscular afferents were the most common fiber type recorded in the PN (63% of the sample), and overall three fourths of PN fibers responded to stretch (muscular and muscular/urothelial fibers) (Fig. 2B, bottom). Whereas no fibers with urothelial-only receptive fields were found in the LSN sample, 9% of the PN fiber sample had receptive fields restricted to the urothelium (and overall almost one quarter of the PN sample responded to urothelial stroking). Like LSN afferents, PN afferents typically had single, punctate receptive fields that, in contrast to LSN afferents, were distributed throughout the bladder (Fig. 2B, top). Interestingly, none of the PN fiber receptive fields that responded to urothelial stroking was located in the area of the base of the bladder, where most LSN receptive fields were located (and very few of which responded to urothelial stroking). No PN afferents exhibited spontaneous activity.

**Dynamic responses to graded von Frey probing**

All LSN and PN afferent fibers displayed graded responses to an ascending series of von Frey probing stimuli (0.16–2.0 g, 3 s). Figure 3, A and D illustrates mean stimulus–response functions to von Frey probing of the receptive fields of the principal LSN (serosal and muscular) and all four PN fiber types, respectively. LSN muscular and serosal afferents appear to be more responsive to probing at lower forces (e.g., 0.40 g), but there were no significant differences in response to probing between fiber types within a pathway or between pathways.

---

**FIG. 3.** Mechanosensitivity, adaptation, and activation characteristics of splanchnic (**left column**) and pelvic (**right column**) nerve afferents to von Frey probing (0.16–2.0 g). All fiber types in both pathways displayed graded responses to increasing intensities of von Frey force (**A, D**). **B** and **E**: mean adaptation profiles (error bars omitted for clarity) during application of a 1-g von Frey probe (3 s). All 4 fibers types in the pelvic pathway (**E**) gave an initial dynamic response to application of the probe, whereas neither muscular nor serosal splanchnic afferents (**B**) responded in this fashion. Sensitivity to von Frey probing was assessed in **C** and **F** by determining the percentage of afferents responding at the 4 intensities of force applied.
Unfortunately, we did not examine responses to a less-intense probing force (e.g., 0.07 g), which may have confirmed greater sensitivity in the LSN pathway.

The only significant difference between pathways is apparent in the response and adaptation to probing (1 g). Responses of serosal and muscular LSN fibers exhibited neither a dynamic response to probing nor adaptation during the 3-s application of the 1-g stimulus (Fig. 3B), whereas all four mechanosensitive fiber types in the PN pathway gave dynamic responses at the onset of stimulus application before adapting to response magnitudes not different from their LSN counterparts (Fig. 3E). Relative to their splanchnic nerve counterparts (Fig. 3B), pelvic nerve serosal (F = 6.83, P = 0.011, Fig. 3E) and muscle (F = 9.16, P = 0.002, Fig. 3E) afferents gave significantly greater dynamic responses (0.0–0.5 s) to probing (1 g), which adapted quickly within 0.5 s of stimulus application.

Percentages of afferents responding to the range of forces applied are compared in Fig. 3, C and F. Chi-square analysis did not reveal any significant differences either within or between pathways.

**RESPONSES TO STRETCH.** Within the PN group of 39 muscular afferent fibers studied, two principal response types are apparent, although there is no obvious difference in location of receptive fields (Fig. 4, A and B). The larger proportion (64%) of fibers had low thresholds for response to stretch, typically responding at the lowest load tested, 1 g. Interestingly, many of them (see Fig. 4D) encoded stimulus intensity throughout the range of loads applied. A smaller proportion (36%) of muscular fibers had high thresholds for response to stretch, responding first at or >10 g. The estimated (by extrapolation) response thresholds for the low- and high-threshold groups are about 1 and about 10 g, respectively; the slopes of their stimulus–response functions do not differ (mean 3.7 for low- and 3.5 for high-threshold fibers). Despite significant differences in response threshold, both low- and high-threshold PN muscle afferents gave initial dynamic responses at the onset of stretch and adapted similarly to steady rates of discharge during the period of stretch (20 g, 20 s; Fig. 4C). The difference between low- and high-threshold PN fiber response and adaptation within the first 5 s of stimulation was significant (F = 23.36, P < 0.0001). Inspection of Figs. 1 and 5 also reveals that responses to stretch are closely linked to stimulus onset and termination.

As suggested by the variability of responses of low-threshold PN muscular fibers to stretch at greater loads (Fig. 4A), there are fibers within the low-threshold sample with different encoding properties (Fig. 4D) (see also Shea et al. 2000; Zagorodnyuk et al. 2006). The majority of low-threshold fibers (16/25) encoded the applied load only at low, physiological intensities of stretch (up to ~10 g) after which response magnitude plateaus. In contrast, 9 of the 25 low-threshold fibers not only encoded the applied load throughout the range of loads applied, but also gave mean maximum responses (206 ± 68 total spikes in 20 s at 25 g) fourfold greater than the

![Fig. 4](http://jn.physiology.org/)

"Characteristics of pelvic nerve muscular fiber responses to stretch. A: low-threshold muscular afferents responded at low stimulus intensity and encoded increasing stimulus intensity throughout the range of loads tested. The estimated response threshold extrapolates to about 1 g. High-threshold muscular afferents did not respond at low intensities of load and first responded at ≥10 g load. The estimated response threshold extrapolates to about 10 g. The difference between low- and high-threshold muscular afferent responses to stretch is significant (F = 7.39, P = 0.007). B: distribution of low- and high-threshold receptive fields. C: both low- and high-threshold muscular afferents gave an initial dynamic response to stretch (20 g) and similarly adapted to relatively stable, but significantly different rates of discharge for the duration of stretch (20 s) (F = 23.36, P < 0.0001). Response magnitudes of low-threshold fibers were on average significantly greater than response magnitudes for high-threshold fibers. D: low-threshold fibers were further divided into encoding and nonencoding types; 16 of the 25 low-threshold fibers encoded stimulus intensity up to about 10 g load and did not further increase response magnitude as load was increased. The remaining 9 low-threshold muscular afferents exhibited load-dependent responses throughout the range of intensities applied."
mean maximum response of high-threshold PN muscular afferents (49 ± 14 total spikes in 20 s at 25 g).

Muscular afferents are not present in the same proportion in the LSN pathway as in the PN pathway and only 10 were quantitatively studied. One of the 10 LSN muscular fibers had a high threshold for response and all of the 9 low-threshold fibers were of the “low encoding” type.

**Sensitization of muscular PN bladder afferent fibers**

We further examined the properties of muscular PN bladder afferents that responded to stretch to determine whether their mecanosensory properties sensitized after exposure to an inflammatory soup (IS, pH 6.0). Figure 5 shows examples of sensitization of low-threshold (Fig. 5A) and high-threshold (Fig. 5B) PN muscular afferents. Responses to stretch are clearly increased when tested 5 min after a 1-min exposure to IS and high-threshold fibers tested in this manner also exhibited a decrease in response threshold to 5 g (Fig. 5B). Figure 5A also illustrates activation of a fiber by IS (i.e., response “during IS”) and in Fig. 5B after-discharge at high intensities of stretch (25 g), an observation not noted in the absence of sensitization. In four experiments, vehicle (pH 6.0) was applied to the receptive fields of two low-threshold and two high-threshold PN muscle afferents. Responses to stretch (1–25 g) were not sensitized when tested either 5 or 20 min after exposure to pH 6.0 vehicle; mean responses were 94 and 95% of prevehicle baseline. Summary data for 17 muscular PN afferents are given in Fig. 6. Data for low-threshold (11) and high-threshold (6) fibers are presented in Fig. 6, A and B, respectively, revealing significant sensitization to stretch 5 and 20 min after exposure to IS (P < 0.01 for low- and high-threshold fibers).
high-threshold afferents at both times of testing). Ten of the 17 PN muscular fibers responded to application of IS, revealing chemosensitivity in addition to mechanosensitivity. Interestingly, no sensitization to von Frey probing was apparent at any force tested (Fig. 6C).

**DISCUSSION**

The present report characterizes mechanosensitive properties of afferent fibers in the LSN and PN innervation of the mouse urinary bladder. We identified four classes of afferent fiber, three of which were common to both pathways. The fourth class of fiber, urothelial fibers that responded to gentle stroking of the urothelium (10 mg), was present only in the PN pathway. The principal findings include clear evidence of differences between the LSN and PN innervation of the urinary bladder with respect to location of receptive fields and proportions of classes of mechanosensitive fibers contained in each pathway. Serosal and muscular afferents represented 97% of the sample of LSN mechanosensitive afferents studied and their receptive endings were located principally near the base of the bladder. Muscular afferents and, overall, stretch sensitivity dominated response properties of PN mechanosensitive afferents; three quarters of the sample responded to stretch and receptive fields were distributed throughout the bladder. These findings suggest significant functional differences between mechanosensitive afferents contained in these pathways.

The difference in distribution of LSN and PN receptive endings in the bladder is consistent with the anatomical distribution of LSN and PN axons in the bladder. In a series of studies in the cat, Uemura and colleagues describe the distributions of sacral (PN) and lumbar (LSN) axons in the urinary bladder. They report that PN axons were distributed equally to all areas of the bladder (Uemura et al. 1973), consistent with the widespread distribution of PN receptive fields in the mouse urinary bladder reported here. They note that terminal axons were more numerous outside muscle fascicles, which they suggested appeared to be tension receptors, a finding not different from the present report where most of the PN afferent fibers responded to stretch/tension. In a subsequent report (Uemura et al. 1974), axons from the lumbar innervation were most numerous in the trigone region, followed by the ventral neck of the bladder. A third report (Uemura et al. 1975) found that 3.7-fold more lumbar than sacral afferent axons innervated the submucosa of the bladder, commenting that this was the reverse ratio when the muscle coat of the bladder was examined. They also confirmed in this study that lumbar axons were concentrated in the bladder neck, whereas sacral afferent axons were evenly distributed throughout the bladder. Their findings in the cat are consistent with the results reported here, with respect to both the distributions of mechanosensitive receptive endings in the mouse bladder (widespread for the PN and concentrated at the base of the bladder for the LSN) and innervation of bladder muscle by the PN and sensitivity to stretch/tension. In the rat, Vera and Nadelhaft (1992) confirmed that the urinary bladder is innervated by axons with cell bodies in the upper lumbar (L1–L3) and lumbosacral (L6–S1) dorsal root ganglia. Interestingly, using two different tracers they found very few double-labeled cells and concluded that the dome and base of the bladder are innervated by separate and distinct neuronal populations.

The function of serosal afferents, which constituted 67% of the LSN pathway, is unclear. Serosal afferents responded optimally and in a graded fashion to punctate (perpendicular) von Frey probing, a decidedly unphysiological stimulus, and not to stretch/tension. We do not consider the probing stimulus to be noxious when applied for 3 s; it was used in the present experiments principally to locate the most sensitive (“hot spot”) part of the receptive field and to characterize receptive endings that did not also respond to either of the other mechanical stimuli tested. One might speculate that activation of multiple serosal afferents during bladder filling or muscle...

---

**FIG. 6.** Summary of low- (A) and high-threshold (B) pelvic nerve (PN) muscular afferent fiber responses to stretch before (baseline) and 5 and 20 min after a 1-min application of IS to the receptive field. Responses to stretch were significantly sensitized by IS. In A, F = 9.23 (P = 0.002) and F = 23.22 (P < 0.0001) vs. baseline at 5 and 20 min, respectively, after exposure to IS. In B, F = 4.73 and F = 6.53 (P = 0.003 for both) vs. baseline at 5 and 20 min, respectively, after exposure to IS. Not only is response magnitude increased after exposure to IS, all high-threshold fibers responded at both times of testing to the 5-g load, representing a reduction in response threshold. C: responses to von Frey probing of PN muscular afferent receptive endings were not sensitized by IS.
contraction or spasm could contribute to a sharp, transient
unpleasant or painful sensation, but the urinary bladder does
not typically experience rapid filling or spasm. Perhaps
these punctate receptive fields are located on or near vas-
cular elements in the bladder wall (e.g., see Floyd et al.
1976), either within the muscle layers or serosa, but we were
unable in this preparation to determine their precise location
within the tissue.

We did not examine either sensitivity to or sensitization by
inflammatory soup of responses of serosal fibers to probing (or
LSN muscular fibers to stretch), and doing so may have
revealed chemosensitivity and/or a role of LSN afferents in
bladder reflexes altered by bladder irritation. Two reports
suggest that the hypogastric nerve, a component of the LSN
pathway, is important to chemosensitivity and perhaps re-
sponses to noxious distension of the bladder (Moss et al. 1997)
as well as changes in urinary frequency caused by chemical
bladder inflammation (Mitsui et al. 2001). It should be noted,
however, that the hypogastric nerve contains axons from both
dorsal root ganglia and sympathetic chain ganglia that reach
the hypogastric nerve through the pelvic nerve as well as from
postganglionic neurons in the major pelvic ganglion (Nadelhaft
and Vera 1991). Accordingly, assignment of nerve function on
the basis of interpretation of multiunit recordings or transection
of the hypogastric nerve is imprecise.

We are aware of no other report studying mechanosensitive
bladder afferents in the splanchnic/hypogastric pathway in the
mouse. A multiunit study in the rat (Moss et al. 1997) and
single-unit studies in the cat (Bahns et al. 1986; Floyd et al.
1976; Winter 1971) have been reported. In the cat, Floyd et al.
(1976) probed the bladder in situ from the serosal side and
found that most hypogastric nerve afferents had multiple,
punctate receptive fields that included sites on both the vascu-
lature and serosa, most of which were restricted to the base of
the bladder. In contrast, Bahns et al. (1986) found only single
mechanosensitive sites on the surface of the serosal side of the
bladder. Both sets of investigators also distended the cat
bladder, Floyd et al. (1976) reporting that hypogastric bladder
afferents exhibited a wide range of response thresholds (a
conclusion arrived at by Winter 1971 as well), whereas Bahns
et al. (1986) reported a narrower range of response thresholds,
concluding that there were no nociceptive visceral afferents in
the hypogastric pathway. The in vitro preparation used here
precluded bladder distension as a stimulus, but 30% of the LSN
innervation of the mouse bladder was responsive to stretch/
tension, suggesting correspondence with results in the cat. We
cannot comment, however, on how representative is the finding
of a high proportion (67%) of serosal afferents in this pathway
in the mouse, although there are clearly hypogastric–LSN
receptive endings that innervate the serosa in cats as well. In a
recent study of colon mechanosensitive afferents in the mouse
LSN pathway, 36% were classified as serosal. In the PN bladder
pathway, serosal afferents represented only 14% of the sample
studied here, a proportion approximately one half the 33% of
serosal afferents described in the mouse PN colon pathway
(Brierley et al. 2004; see Fig. 7 for summary). Serosal bladder
afferents in the LSN pathway may be more sensitive to lower
intensities of stimulation than their PN counterparts, perhaps
suggesting a functional role in the sensation of bladder filling.
The data presented here, however, cannot confirm this suppo-
sition.

The relative proportions of muscular afferents in the bladder
LSN and PN pathways are near the opposite of the proportions
of serosal afferents; muscular afferents constituted 63% of the
PN pathway and 30% of the LSN pathway. Muscular afferents
in both pathways exhibited indistinguishable responses to von
Frey probing with the exception that PN afferents exhibited
dynamic responses at the onset of the 1-g von Frey stimulus
(which were absent in LSN afferents). Muscular afferents in
hollow organs are widely considered to be functionally impor-

![Fig. 7. Summary of proportions of affer-
enet fiber types in the mouse splanchnic (left
column) and pelvic (right column) pathways
for urinary bladder (top row) and colon (bot-
ttom row). Data for mouse colonic afferents
were adopted from Brierley et al. (2004).](http://jn.physiology.org/)

J Neurophysiol • VOL 99 • JANUARY 2008 • www.jn.org
tant to sensations of organ filling (low-threshold afferents) and discomfort and pain (high-threshold afferents) when organs are overfilled/overdistended. Normally, high-threshold afferents likely function as nociceptors in response to acute stimuli, but given that both low- and high-threshold afferents sensitize (a characteristic of nonvisceral nociceptors) and both can encode into the noxious range, it is likely that both low- and high-threshold stretch-sensitive endings in hollow organs contribute to discomfort and pain in the presence of organ inflammation (see subsequent Discussion). It has been generally held that both innocuous, physiological filling of the urinary bladder and bladder pain are signaled mainly by pelvic afferents and principally by those that respond to stretch (Kuru 1965). This interpretation, first, discounts the significant proportion of muscular afferents contained in the LSN pathway and, second, is not consistent with other literature cited here.

As has been described for other hollow organs, we found stretch-sensitive muscular afferents with low and with high thresholds for response in both the LSN and PN bladder innervation, although the proportions differed between the two pathways. In a related in vitro study of stretch-sensitive PN bladder afferents in the guinea pig, Zagorodnyuk et al. (2006) described stretch-sensitive mechanoreceptors that they termed muscle mechanoreceptors, three quarters of which had low thresholds for response and one quarter of which had response thresholds approximately eightfold greater and were considered by them to be high-threshold muscle mechanoreceptors. They also described bladder PN tension–mucosal mechanoreceptors similar in characteristics to the muscular/urothelial class of afferents described in the present report and mucosal mechanoreceptors that were stretch insensitive, findings consistent with the present report. Recently, Daly et al. (2007) reported that 80% of mechanosensitive PN afferent fibers innervating the mouse urinary bladder were of the low-threshold type. They similarly report both dynamic and static/stable components to the response to filling pressure. Interestingly, they also observed that the response magnitude of low-threshold fibers was on average greater than the response magnitude of high-threshold fibers. In the present study, 35% of the 39 fibers studied had high thresholds for response, a proportion of the sample greater than that reported in studies in the rat (Sengupta and Gebhart 1994; Shea et al. 2000) and greater than that in the recent study by Daly et al. (2007) in the mouse. This may reflect differences between bladder filling as a stimulus as opposed to stretch in vitro and remains to be established.

Sensitization is a characteristic of nociceptors defined originally as an increase in response magnitude to a suprathreshold noxious intensity of stimulation after skin insult and a reduction in response threshold (Bessou and Perl 1969). Afferent fiber sensitization reflects an increase in the excitability of the receptive ending and has been demonstrated as important to the development of hyperalgesia/hypersensitivity, including visceral hypersensitivity. In previous reports (e.g., Handwerker and Reeh 1991; Jones et al. 2005; Su and Gebhart 1998) and in the present report, we used an inflammatory soup applied to bladder receptive endings to study chemosensitivity and sensitization of PN muscular afferents. It should be acknowledged that bradykinin, a component of the inflammatory soup, can cause smooth muscle contraction and thus confound interpretation of studies such as described here. We believe this to be unlikely, however, because the inflammatory soup did not reliably excite receptive endings and responses to probing were unaffected. As previously documented for PN afferents innervating the mouse (Jones et al. 2005) and rat (Su and Gebhart 1998) colon, the inflammatory soup reliably sensitized responses to bladder stretch, as reflected in the increase in response magnitude of both low- and high-threshold PN muscle afferents to stretch and the reduction in response threshold for high-threshold afferents. Rong et al. (2002) also documented sensitization of both low- and high-threshold PN bladder afferents responsive to bladder filling by the P2X3 receptor agonist α,β-methylene adenosine triphosphate (ATP), supporting a role for endogenous ATP in increasing excitability of bladder afferents.

The significance of these outcomes to bladder sensation is several-fold. First, bladder muscular afferents that normally respond at a low rate of discharge to filling in the physiological range discharge when sensitized at greater rates to the same low-intensity stimuli. Significantly, it appears that some of the low-encoding, low-threshold muscular afferents exhibit high encoding properties after exposure to inflammatory mediators. Second, high-threshold afferents that previously did not respond to intensities in the low physiological range exhibited a reduction in response threshold to 5 g when sensitized and continued to exhibit increased sensitivity for the duration of testing, which was terminated after 20 min. Finally, given that low- and high-threshold bladder afferents can encode stretch/distending stimuli into the noxious range and also sensitize, stretch/distension sensitive afferents appear to be able to contribute to discomfort and pain. Together, these data confirm previous reports of sensitization of visceral afferents innervating hollow organs and suggest, for the bladder, that discomfort and pain can be generated by normal bladder filling in circumstances of interstitial cystitis/painful bladder syndrome.
