ABSTRACT

Nitric oxide (NO) is generated by multiple cell types in the vertebrate retina, including amacrine cells. We investigate the role of NO in the modulation of synaptic function using a culture system containing identified retinal amacrine cells. We find that moderate concentrations of NO alter GABA<sub>A</sub> receptor function to produce an enhancement of the GABA-gated current. Higher concentrations of NO also enhance GABA-gated currents, but this enhancement is primarily due to a substantial positive shift in the reversal potential of the current. Several pieces of evidence, including a similar effect on glycine-gated currents, indicate that the positive shift is due to an increase in cytosolic Cl<sup>-</sup>. This change in the chloride distribution is especially significant because it can invert the sign of GABA- and glycine-gated voltage responses. Furthermore, current and voltage clamp recordings from synaptic pairs of GABAergic amacrine cells demonstrate that NO transiently converts signaling at GABAergic synapses from inhibition to excitation. Persistence of the NO-induced shift in E<sub>Cl</sub> in the absence of extracellular Cl<sup>-</sup> indicates that the increase in cytosolic Cl<sup>-</sup> is due to release of Cl<sup>-</sup> from an internal store. An NO-dependent release of Cl<sup>-</sup> from an internal store is also demonstrated for rat hippocampal neurons indicating that this mechanism is not restricted to the avian retina. Thus, signaling in the CNS can be fundamentally altered by an NO-dependent mobilization of an internal Cl<sup>-</sup> store.
INTRODUCTION

Amacrine cells are interneurons in the inner retina that extend laterally and form synaptic connections with bipolar cells, ganglion cells, and other amacrine cells. These lateral interactions play a key role in determining the nature of retinal output (for reviews, see Lagnado 1998; Taylor and Vaney 2003) so understanding the function and regulation of amacrine cells is critical to understanding retinal signal processing.

Nitric oxide (NO) has been implicated as a signaling molecule at all levels of the visual system (for review, see Cudeiro and Rivadulla 1999). Nitric oxide synthase (NOS) catalyzes the production of NO and citrulline from arginine. The neuronal form of this enzyme (nNOS) is constitutively expressed and stimulated by elevations of cytosolic Ca\(^{2+}\). In the canonical pathway, NO stimulates soluble guanylate cyclase (sGC) activity. NO is also known to affect target protein function through S-nitrosylation (Stamler et al. 1997; Davis et al. 2001) and by other direct interactions including formation of dinitrosyl iron complexes (Rogers et al. 2003).

Neuronal NOS has been found in subsets of each class of neuron in the vertebrate retina (Kim et al. 1999; Chun et al. 1999; Shin et al. 1999; Blute and Eldred 1997; Fischer and Stell 1999, Rios et al. 2000) and NO itself has been detected in a similar array of retinal cells (Neal et al. 1998; Blute et al. 2000, 2003). In the chicken retina, a subset of amacrine cells expresses high levels of nNOS, and distinct sublaminae of nNOS labeling occur throughout the inner plexiform layer of the retina (Fischer and Stell 1999; Rios et al. 2000; Crousillac et al. 2003). Furthermore, measurements at the inner surface of the retina indicate that this tissue can generate high (micromolar) levels of NO (Donati et al. 1995; Heiduschka and Thanos 1998; Groppe et al. 2003).
The physiological effects of NO production have been examined for some cell types that signal in the inner retina. In the rabbit retina, NO reduces gap-junction coupling between AII amacrine cells and cone bipolar cells (Mills and Massey 1995). Wexler and colleagues, (1998) have shown that NO depresses GABA_A receptor function in cultured rat amacrine cells. In the ferret retina, recordings of ganglion cell activity reveal a dramatic NO-dependent decrease in light responses (Wang et al. 2003). Although effects of NO have been identified in multiple retinal cell types, the full range of NO function in the inner retina remains unknown.

To further examine how NO influences amacrine cell signaling, whole cell recordings were made from cultured GABAergic amacrine cells and amacrine cell synaptic pairs derived from embryonic chick retinas. We show that NO alters amacrine cell activity by affecting the functional properties of GABA_A receptors and, much more dramatically, by converting inhibitory synapses to excitatory synapses through a GABA receptor-independent mechanism. This mechanism involves an NO-induced redistribution of Cl\(^-\). Our results indicate that the redistribution of Cl\(^-\) does not stem from Cl\(^-\) moving across the plasma membrane but is instead due to release of Cl\(^-\) from an internal compartment.

**MATERIALS AND METHODS**

**Cell Culture**

Retinal cultures were prepared from 8 day chick embryos and maintained as previously described (Hoffpauir and Gleason 2002). Experiments were performed on isolated amacrine cells or isolated pairs of amacrine cells 6-14 days (EE 14 – PE 1) after plating. After 6 days in culture, these cells are considered to be mature, based on several
physiological criteria including expression of the appropriate voltage- and ligand-gated ion channels (Huba and Hoffman 1991; Huba et al. 1992) and the formation of functional GABAergic synapses with other GABAergic amacrine cells. The properties of the amacrine-to-amacrine cell GABAergic synapses formed in culture have been previously characterized (Gleason et al. 1993). The uniformity of neurotransmitter phenotype indicates that the amacrine cells in culture represent a subset of amacrine cell phenotypes found in the intact retina.

Hippocampal cultures were made from 18 day rat (Fischer 344) embryos. Micro dissected hippocampal tissue was obtained from Neuromics (Bloomington, MN) and prepared and maintained according to the supplier’s protocols. Recordings from single hippocampal neurons were made after 4-7 days in culture. No physiological assessments of the relative maturity of these cells have been made. According to their developmental timeline alone, they would be considered embryonic (EE 22-EE 25).

Electrophysiology

Whole cell recordings were made using an Axopatch 1-D amplifier, Digidata 1322A data acquisition board, and Clampex 9.2 software (Axon Instruments, Union City, CA). A reference Ag/AgCl pellet in 3M KCl was connected to the culture dish via an agar bridge containing 3M KCl. Patch electrodes were pulled from thick-walled borosilicate glass (1.5 mm O.D., 0.86 mm I.D.; Sutter Instruments, Novato, CA) using a Flaming/Brown Puller (Sutter Instruments). Tip resistance values were 5-10 MΩ for ruptured-patch recordings and 3-5 MΩ for perforated-patch recordings as measured in the bath. All recordings were made at room temperature (22-24°C) and were corrected for junction potential error. Voltage ramp data were leak-subtracted. Because we used both
perforated and ruptured patch to study the NO-shift in \( E_{GABA} \) (see Results), we wanted to
determine whether the recording configuration had an effect on the amplitude of the shift.
To achieve this, we recorded NO-induced shifts in \( E_{GABA} \) on one day with one batch of
NO solution. For these experiments we alternated between the two recording
configurations and found no significant differences in the amplitude of the shifts (\( n=3 \) in
each configuration; \( p=0.999 \)).

**Solutions**

Unless otherwise indicated, all reagents were purchased from Sigma, St. Louis, MO. GABA application was achieved in 10-20 ms through computer-controlled
perfusion barrel movements. This method was also used to switch between normal and
zero external Cl\(^-\) for the experiment depicted in Fig. 8 A. All other solution changes were
achieved in approximately 500 ms by opening and closing the valves upstream of a
manifold feeding one common barrel. The compositions of external and internal
solutions are shown in Tables 1 and 2, respectively. TTX (300 nM) and LaCl\(_3\) (25-50
\( \mu \)M) were added to external solutions (with the exception of the zero Cl\(^-\) external
solution) for single-cell voltage clamp (but not current clamp) recordings to block
voltage-gated Na\(^+\) and Ca\(^{2+}\) currents, respectively. For ruptured-patch recordings, the
following reagents were added to internal solutions (Cs\(^+\)-A, unless otherwise indicated):
50 U/ml creatine phosphokinase, 3 mM adenosine 5’-triphosphate (ATP) dipotassium
salt, 1 mM ATP-disodium salt, 20 mM phosphocreatine (Calbiochem, La Jolla, CA), 2
mM guanosine 5’-triphosphate (GTP) sodium salt. For perforated patch recordings,
either amphotericin B (synaptic pairs, Fig. 4) or gramicidin (Figs. 5 and 6) were added to
normal internal or Cs\(^+\)-internal, respectively to a final concentration of 10 \( \mu \)g/mL.

Contents of external recording solutions are given in mM. Abbreviations are as follows: NMG, N-methyl-D-glucamine; TEA, tetraethylamonium; iseth, isethionate. The pH of external solutions was adjusted to 7.4 using an appropriate base. Glucose concentration was varied ± 10% to alleviate deviations from the normal osmolarity for some of the solutions.

Contents of internal recording solutions are given in mM. Methane sulfonate is abbreviated MES. Internal solutions Cs⁺-A and High Cl⁻ were supplemented with the ATP regeneration system components (see Materials and Methods). Cs⁺-H was supplemented with 2 mM disodium ATP. The pH of the internal solutions was adjusted to 7.4 using an appropriate acid or base.
S-Nitroso-N-acetyl-D,L-penicillamine (SNAP), 1-Hydroxy-2-oxo-3-(N-ethyl-2-aminoethyl)-3-ethyl-1-triazene (NOC-12), 2,2'-(Hydroxynitrosohydrazino)bisethanamine (NOC-18), and 2-(4-Carboxyphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide, sodium salt (Carboxy-PTIO) were obtained from Dojindo Molecular Technologies, Inc. (Gaithersburg, MD) and stored at –20°C. The final pH of external solutions containing the nitric oxide donors was readjusted to 7.4 with NaOH (SNAP and NOC 12). 1H-[1,2,4]Oxadiazolo[4,3-a]quinoxalin-1-one (ODQ) was prepared at 10 mM in DMSO. Furosemide and Bumetanide were prepared as 300 mM stocks in DMSO.

**NO-bubbled solutions**

Pure NO solutions were prepared by bubbling solutions with argon for 15 minutes followed by 15 minutes of bubbling with pure soda lime-filtered NO. NO solutions were tightly sealed, protected from light and stored at 4°C. Although the method for preparing NO was standardized, the efficacy of different batches was variable. For most experiments, injections between 20-50 µL were able to elicit shifts of 15-35 mV. When standard volumes of a batch of NO solution became less efficient, a new batch was obtained. The NO solutions were delivered into the perfusion system manually with a Hamilton Syringe via in-line injections (20-50 µL depending on potency, see below). In-line injection of dye-containing solutions indicated that NO exposure was limited to 1-3 seconds with most of the NO arriving in the first 500 ms. NO was bubbled into either H₂O or TEA external. No differences in the effects of NO in the two solutions were observed. For synaptic recordings, NO was bubbled into a 40mM HEPES solution to minimize low pH effects on Ca²⁺ channels and other synaptic proteins. The concentration of NO in these solutions was measured using an ISO-Nitric Oxide meter.
(NOMK2 system) with an ISO-NOP electrode (World Precision Instrument, Sarasota, FL) for a batch and volume that was demonstrated to be effective in eliciting cellular responses. The mean NO concentration measured at the perfusion outlet was 2.0 +/- 0.3 µM. This value represents the upper limit of NO coming in contact with a cell. For SNAP solutions, about 100 nM NO was detected in external solution containing 250 µM SNAP (2 hr after preparation). With the exception of Figure 1, the data shown were obtained using NO-bubbled solutions.

“Air-exposed” NO solutions were made by exposing NO-bubbled solution to air for at least 10-30 min. For both fresh and air-exposed NO solutions, pH values typically ranged between 2 and 3. Injections of the appropriate amount of pH 2.5, NO-free solutions were routinely used as controls and none of the effects reported here were reproduced by low pH alone. Although extreme care has been taken to standardize the preparation, handling and injections of these volatile solutions, some variability remains. As such, only those cells receiving the same volumes, from the same batch of NO-bubbled solutions were used for quantitative comparisons. Data are reported as means ± standard deviation and statistical significance was determined using the t-test. Data shown in Figs 5 B D and 6 F were analyzed using the paired t-test.

RESULTS

The effects of NO on GABA-gated currents

To explore the effects of NO, we recorded whole-cell GABA_A receptor currents (Hoffpauir and Gleason 2002) from individual amacrine cells. For these experiments, Cs⁺-A internal and TEA-A external solutions were used, and recordings were made in the ruptured-patch recording configuration. Under these conditions, we find that NO
produces three effects in amacrine cells. First, moderate NO donor concentrations (250 µM SNAP, ~100 nM NO, see Materials and Methods) caused a small (~15%) enhancement of the GABA-gated current amplitude that was not due to alteration in the reversal potential of the current (E\(_{\text{GABA}}\), Fig. 1). Similar effects were observed with NOC 12 (250µM) and NOC 18 (300µM, not shown). The SNAP-dependent enhancement was significantly inhibited in the presence of the NO scavenger carboxy-PTIO indicating that NO rather than donor end products underlie the GABA\(_{\text{A}}\) current enhancement (Fig. 1 C, p=0.002).

**Figure 1.** Moderate concentrations of NO enhance GABA\(_{\text{A}}\) receptor function. **A**, Peak current amplitudes of inward currents elicited by 500-ms applications of GABA (20 µM) are normalized to the current amplitude just prior to application of SNAP. **B**, Whole cell voltage-clamp recordings of GABA-gated currents from a representative amacrine cell recorded before (black trace) and in the presence of (gray trace) SNAP. Scale bars are 100 pA and 500 ms. **C**, Mean response amplitudes from cells exposed to two concentrations of SNAP and in the presence of the NO scavenger, carboxy PTIO. Mean current change is calculated as the percent difference of GABA-gated current amplitudes measured immediately before SNAP application compared to those measured after 30 seconds of exposure to SNAP. **D**, Leak-subtracted currents elicited by voltage ramps delivered in the presence of GABA before (black trace), and in the presence of (gray trace) SNAP (500 µM). Scale bars are 100 pA and 10 mV. All recordings were made with Cs\(^+\)-A internal and TEA-A external in the ruptured-patch configuration.
Second, higher concentrations of NO (100’s of nanomolar to low micromolar, NO-bubbled solutions, see Materials and Methods) produced a transient (1-3 sec), GABA-independent inward current (Fig. 2 A, C; Fig. 7 B-i, asterisks). Based on reversal potential measurements, this NO-dependent, GABA-independent, inward current is a cation current ($E_{rev} = +23.4 \pm 6.6$mV, n=5).

Figure 2. Higher concentrations of NO promote a positive shift in $E_{GABA}$. Top traces in A and B are raw data from ruptured-patch voltage clamp recordings of GABA-gated currents from a representative cell before and after NO application. GABA pulses (20 $\mu$M) were 300 ms in duration and are indicated by horizontal bars. A, Whole cell, voltage clamp recordings (Cs$^+$-A internal and TEA-A external) of GABA-
gated currents reveal that higher concentrations of NO induce a transient, several-fold enhancement of GABA-gated currents. Asterisk indicates NO-dependent current observed prior to the second GABA application. B. The same experiment as in A, using air-exposed NO solution. Raw data in A and B are from same cell. Scale bars are 150 pA, 1 sec. C. An amacrine cell is held at the predicted \( E_{\text{GABA}} \). GABA is applied for 300 ms during each trace. No GABA-gated currents are observed until application of NO. Asterisk denotes NO-dependent current. Scale bars are 25 pA, 5 sec. D. Voltage ramps in GABA were delivered before and after addition of NO. Leak-subtracted currents reveal a shift in \( E_{\text{GABA}} \) after NO application (gray trace). Inset, Subtraction of the NO-induced shift in reversal potential reveals an increase in the slope of the GABA-gated current-voltage relationship after NO injection (gray trace). Scale bars are 100 pA, 20 mV. E. Mean \( E_{\text{GABA}} \) values are plotted over time. F. Representative GABA-gated currents from voltage ramps delivered after a 11 minute treatment with ODQ (2 \( \mu \)M). Black trace, before NO injection; Grey trace, after NO injection. G, ODQ did not block the NO-induced shift in \( E_{\text{GABA}} \) (p=0.83, n=5).

The third effect of NO is the most dramatic and will form the main focus of this work. We find that brief (1-3 sec) exposure to higher NO concentrations also produced a several-fold enhancement of the GABA-gated current (Fig. 2 A) due to a transient positive shift in \( E_{\text{GABA}} \) (shift = 24.8 ± 4.2 mV; Fig. 2 C-E). The slight inhibition of GABA-gated current amplitude after exposure to air-exposed NO solution (Fig. 2 B) is most likely due to the acidic nature of these solutions (see Materials and Methods, Huang and Dillon, 1999). Note that the time course of recovery for the (higher concentration) NO-induced current enhancement (Fig. 2 A) is consistent with the recovery time course for \( E_{\text{GABA}} \) (Fig. 2 E). Similar shifts in \( E_{\text{GABA}} \) were obtained with high concentrations (1mM) of the NO donor NOC 12 (not shown) indicating that the mechanism responsible for the shift in \( E_{\text{GABA}} \) can be activated by either NO delivery method as long as the concentration of NO is in the correct concentration range. A small increase in the slope of the IV relationship for the GABA-gated current (first NO effect) was also detectable with higher NO concentrations (Fig. 2 D, inset). The role of soluble guanylate cyclase (sGC) activation in the NO-induced shift in \( E_{\text{GABA}} \) was investigated using the sGC inhibitor ODQ. Prolonged (>10 min) pre-incubation with the inhibitor did not block the NO-induced shift in \( E_{\text{GABA}} \) indicating that sGC activity is not involved in this mechanism.
The non-significant trend towards larger responses in ODQ suggests that basal sGC activity might have a suppressive effect on the mechanism underlying the shift in $E_{\text{GABA}}$. Finally, the NO-dependent current (second NO effect) may be related to the shift in $E_{\text{GABA}}$, but does not seem to be an absolute requirement because we have observed the shift in the absence of this current.

**The NO-induced shift in $E_{\text{GABA}}$ is due an elevation in cytosolic Cl⁻.**

Three possible explanations for the NO-induced shift in $E_{\text{GABA}}$ were examined: 1) a change in ion selectivity of the GABA$_A$ receptors, 2) the introduction of another permeant anion into the cell, or 3) an increase in intracellular Cl⁻ concentration. To determine whether NO increases the selectivity of GABA$_A$ receptors to acetate (the only other anion in the internal solution), internal acetate was substituted with methanesulfonate, a bulky anion unlikely to permeate the receptors. This substitution, however, did not prevent the NO-induced shift in $E_{\text{GABA}}$ as indicated by the several-fold enhancement of the GABA-gated current (Fig. 3 A). This suggests that the NO-induced shift in $E_{\text{GABA}}$ is not due to a change in the ion selectivity of the channels.

The shift could be due to the production of nitrate (NO$_3^-$) that occurs when NO reacts with O$_2$ and H$_2$O. Because NO$_3^-$ is quite permeable through GABA$_A$ receptors (Biscoe and Duchen 1985; Bormann et al. 1987), it is possible that trapped cytosolic NO$_3^-$ (from inwardly diffusing NO) contributes to the shift in $E_{\text{GABA}}$. Furthermore, although the recording solutions are HCO$_3^-$-free, it is also possible that NO transiently stimulates the production of HCO$_3^-$, another anion that can permeate GABA$_A$ receptors (Bormann et al. 1987). In zero Cl⁻ internal and zero Cl⁻ external solutions, no GABA-gated currents were observed either before or after application of NO (Fig. 3 B). This argues against the
possibility that the shift is due to an increase in intracellular $\text{NO}_3^-$, or $\text{HCO}_3^-$ or any other permeant anion.

Figure 3. The shift in $E_{\text{GABA}}$ is due to an NO-induced increase in cytosolic Cl$. A$, Substituting methanesulfonate for acetate in the Cs+ internal (MES internal) solution does not prevent NO-induced enhancement. The NO-dependent current (asterisk) is also observed with this internal solution. Experiment conducted as in Figure 2A and B, with horizontal bars indicating time course of GABA application. $B$, Ruptured-patch, voltage-clamp recordings of an amacrine cell held at $-70 \text{ mV}$ with 0 Cl internal and external solutions. GABA is applied for 300 ms in each trace (horizontal bars). Time scale applies only to current traces (start to start intervals are 5 sec). An NO-dependent current was recorded immediately after the NO application (not shown). Scale bars ($A$ and $B$) are 10 pA, 1 sec. $C$, Leak-subtracted currents from voltage ramps delivered in GABA (20 µM) and glycine (20 µM) before (black
trace) and after (gray trace) addition of NO. (Cs\(^+\)-A internal and TEA-A external solutions). **D.** Current clamp recordings from a different cell (\(V_{rest} = -65\) mV) show the voltage responses to GABA and glycine before (black trace) and after (gray trace) exposure to NO. An action potential occurs at the beginning of the glycine-induced depolarization. Scale bars are 10 mV, 500 msec. (normal internal and normal external solutions).

If the effect of NO is to raise internal Cl\(^-\), then a similar shift in reversal potential should also be observed when glycine receptors are activated. Agonist-gated currents were elicited with pulses of 20 µM glycine or 20 µM GABA delivered during voltage ramps. Addition of NO caused a shift in the reversal potential to more positive values for both agonists (Fig. 3 C; GABA shift: 33.6 ± 11.5 mV; glycine shift: 30.0 ± 14.0 mV; \(p=0.67\); \(n=5\)) indicating that NO is stimulating a redistribution of Cl\(^-\) in these cells. An increase in the slope of the glycine-gated current was also observed indicating an enhancing effect of NO on glycine receptor function. The ability to change the internal Cl\(^-\) concentration in the face of diffusion from the pipet may be unexpected but it is not unprecedented. Cl\(^-\) transport has been shown to be effective in opposing diffusion from the recording pipet (Staley et al. 1996) and changes in cytosolic Cl\(^-\) have been measured by optical methods in the ruptured patch recording configuration (Isomura et al. 2003). It is also possible that the redistribution of Cl\(^-\) is not a global event but one that occurs locally, possibly in neuronal processes.

Current clamp recordings were made to determine how the NO-induced shift in \(E_{Cl^-}\) affects GABA- and glycine-dependent changes in membrane potential (Fig. 3 D). Resting membrane potentials were -60.1 ± 13.2 mV (\(n=5\)). Under control conditions, application of GABA or glycine hyperpolarized these cells to -70.9± 2.7 mV and -68.7 ± 5.3 mV, respectively. For the first agonist pulse after NO application, GABA depolarized the cells to -31.8 ± 25.2 mV and glycine depolarized the cells to -34.4 ± 18.4
mV. One cell responded to both GABA (not shown) and glycine (Fig. 3 D) with a single action potential followed by a steady depolarization. This is the typical voltage response for these cells given sufficient depolarization (Gleason et al. 1993). It is important to note, however, that action potentials are not required for Ca$_{2+}$-dependent neurotransmitter release from these cells (Gleason et al. 1993). These current clamp recordings demonstrate that NO can change the sign of whole–cell voltage responses to GABA and glycine.

**The NO-induced shift in $E_{Cl^-}$ occurs at synapses**

To examine the influence of NO specifically at retinal amacrine cell synapses, dual perforated patch recordings were made from pairs of cultured GABAergic amacrine cells. It is well established that GABAergic amacrine cell synapses are normally inhibitory, both in the retina (Lagnado 1998) and in these cultures (Gleason et al. 1993). Recordings from isolated pairs of amacrine cells demonstrate that brief exposure to NO can transiently change the sign of GABAergic synapses (Fig. 4). With both pre- and postsynaptic cells in the voltage clamp configuration, a depolarizing voltage step in the presynaptic cell produced a small outward current in the postsynaptic cell. After NO, postsynaptic currents become inward indicating an excitatory effect on the postsynaptic cell (Fig. 4 A, gray trace). The relatively small, noisy postsynaptic currents are consistent with the low release rates described for these synapses in culture (Gleason et al. 1993) and for GABAergic amacrine cell synapses in the intact retina (Zheng et al. 2004). When the postsynaptic cell is switched to current clamp, the postsynaptic response is barely detectable because under control conditions, the resting potential of the cell (-67 mV) is
very near the calculated $E_{Cl}$ (-70 mV). After NO, the postsynaptic voltage response is depolarizing (Fig. 4 B, gray trace).

**Figure 4.** NO inverts the sign of GABAergic synapses. **A,** Both pre- and postsynaptic cells were voltage clamped. Only data from the postsynaptic cell are shown. Under control conditions, depolarization of the presynaptic cell from -70 mV to -10 mV elicits a small outward current in the postsynaptic cell (black trace, $V_{hold}$= -66 mV). After NO, depolarization of the presynaptic cell produces a large inward current in the postsynaptic cell (gray trace). Traces immediately following NO application were contaminated by the NO-dependent current. The trace shown was collected about 15 sec after NO. NO exposure time is 2-3 sec (See Materials and Methods) Scale bars are 200 pA, 50 msec. **B,** Current clamp recordings from the same postsynaptic cell as in **A.** Depolarization of the presynaptic cell (to 0 mV, in voltage clamp) produces only a slight hyperpolarization in the postsynaptic cell (black trace) because the resting potential of this cell (-67 mV) is near the predicted $E_{Cl}$ (-70 mV). A record collected about twenty seconds after NO exposure shows that the postsynaptic response is now depolarizing (gray trace). Scale bars are 5 mV, 100 msec. Records were collected with normal internal containing amphotericin B and TEA-A external solutions.

NO-dependent, excitatory synaptic responses were detected in all pairs examined (n=5).

Postsynaptic responses to subsequent presynaptic depolarizations were omitted from Figure 4 for clarity, but they show that recovery from the NO-dependent shift in $E_{Cl}$ occurs over a similar time frame as observed in recordings of whole-cell GABA-gated
currents in single amacrine cells (see Fig. 2 A, E). It is possible that NO has other, as yet uncharacterized effects on amacrine cell synapses (Hölscher 1997; Ahern et al. 2002), but the key observation here is that the shift in $E_{\text{Cl}}$ found in whole cell recordings also occurs at synapses.

**NKCC does not mediate the increase in cytosolic $\text{Cl}^-$**

What mechanism underlies the increase in cytosolic $\text{Cl}^-$? The plasma membrane $\text{Na}^+\cdot\text{K}^+\cdot\text{Cl}^-$ co-transporter (NKCC) and the $\text{K}^+\cdot\text{Cl}^-$ co-transporter (KCC2) are $\text{Cl}^-$ co-transport mechanisms known to regulate the distribution of $\text{Cl}^-$ across neuronal plasma membranes (Kakazu et al. 2000; Russell 2000). It is now well established that changes in $\text{Cl}^-$ co-transporter expression determine the effects of GABA during development (for review see Payne et al. 2003). In the adult retina, $E_{\text{Cl}}$ varies among cell types and subcellular locations, and this correlates with the expression pattern of NKCC and KCC2 (Vardi et al. 2000). Furthermore, the response properties of retinal starburst amacrine cells are dependent upon the activity of NKCC and KCC2 (Gavrikov et al. 2003). Given the established role of these transporters in determining $E_{\text{Cl}}$, we investigated the role of NKCC and KCC2 in the NO-induced shift in $E_{\text{Cl}}$.

NKCC typically transports 2 $\text{Cl}^-$, 1 $\text{Na}^+$, and 1 $\text{K}^+$ into the cell and the neuron specific $\text{K}^+\cdot\text{Cl}^-$ co-transporter, KCC2, transports 1 $\text{Cl}^-$ and 1 $\text{K}^+$ out of the cell. Thus, the NO-induced shift in $E_{\text{GABA}}$ could be due to an increase in NKCC activity or a decrease in KCC2 activity. To determine if these mechanisms were involved, perforated-patch recordings were made with $\text{Cl}^-$-impermeant gramicidin in the pipet and the co-transport inhibitors, bumetanide (300 µM) and furosemide (300 µM) were used to block NKCC
and KCC2 activity. Both inhibitors shifted $E_{Cl^-}$ to more negative potentials, indicating a dominant inhibitory effect on NKCC (Fig. 5 A, C).

Figure 5. Inhibition of NKCC and KCC Cl- co-transporters does not block the NO-induced shift in $E_{Cl^-}$. A and C, Leak-subtracted currents from voltage ramps delivered in the presence of GABA under control conditions (no NO), in the presence of inhibitor (bumetanide (B) or furosemide (F)), and after NO exposure in bumetanide or furosemide-containing solutions (gray trace). Records were obtained in the perforated patch configuration with gramicidin in the pipette (Cs⁺-B internal, TEA-A external). B and D, Cl- co-transporter inhibitors do not significantly (bumetanide $p=0.66$; furosemide $p=0.17$) reduce the NO-induced shift in $E_{Cl^-}$. NO-induced shifts in $E_{Cl^-}$ in the presence of each inhibitor were compared to control applications of NO in the same cells.

Neither blocker, however, inhibited the NO-induced shift in $E_{Cl^-}$ (Fig. 5 B, D). To assess the variability of responses under control conditions, the effects of two separate NO applications were also examined and we found no significant difference between the two trials ($p=0.69$, $n=5$, not shown). At lower concentrations (10 µM), bumetanide is
selective for NKCC (Russell 2000). In similar experiments, bumetanide at 10 µM was also ineffective in blocking the shift in $E_{Cl^{-}}$ (not shown).

Removal of the externally required co-transported ions shifted $E_{Cl^{-}}$ to more negative potentials. Furthermore, for those cells that were exposed to both zero $K^{+}$ and zero $Na^{+}$ solutions, $E_{Cl^{-}}$ was considerably more negative in zero $K^{+}$ solutions than in zero $Na^{+}$ solutions (Fig. 6A). In some cases, switching to zero $K^{+}$ shifted $E_{Cl^{-}}$ by tens of mVs.

**Figure 6.** Removal of co-transported ions does not block the NO-induced shift in $E_{Cl^{-}}$. A-E, Perforated patch voltage-clamp recordings made with gramicidin (Cs⁺-B internal, TEA-A external). Voltage ramps were delivered in the presence of GABA for each condition and leak-subtracted currents are shown. A, $E_{Cl^{-}}$ is negatively shifted in external solutions lacking $K^{+}$ or $Na^{+}$. Overall, the shift from normal solutions was greater in solutions with zero external $K^{+}$ than in solutions with zero external $Na^{+}$. B, Switching from normal to zero $K^{+}$ external solutions can produce large negative shifts in $E_{Cl^{-}}$. Dotted gray trace shows estimated $E_{Cl^{-}}$ in zero external $K^{+}$. Zero $K^{+}$ external solution was applied for 15 seconds before collecting the 0 $K^{+}$ trace. C-E, Bathing the cells in zero $Na^{+}$, zero $K^{+}$, or zero $Na^{+}$/$K^{+}$ external solutions did not prevent the NO-induced shift in $E_{Cl^{-}}$ (gray traces). F, Average NO-induced shifts in $E_{Cl^{-}}$ for cells bathed in zero $Na^{+}$ or zero $K^{+}$ external solutions are not significantly different from control (0 $Na^{+}$, p=0.17; 0 $K^{+}$, p=0.26).
in as few as 15 seconds (Fig. 6B). These results are consistent with the prediction that zero external K\(^+\) would prevent inward Cl\(^-\) transport through NKCC and promote outward Cl\(^-\) transport through KCC2. Despite these effects, none of these manipulations blocked the NO-induced shift in E\(_{Cl^-}\) (Fig. 6 C-E). Figure 6 F shows that removal of co-
transported ions did not cause a statistically significant (p=0.26; 0.17) change in the magnitude of the NO-induced shift in E\(_{Cl^-}\). Interestingly, a non-significant trend towards larger shifts was observed in the absence of co-transported ions. This may relate to an enhanced Cl\(^-\) gradient between the cytosol and an internal compartment (see below). The roles of two other known plasma membrane Cl\(^-\) transport mechanisms have also been investigated. Neither 4,4\(^{\prime}\)-Diisothiocyanatostilbene-2,2\(^{\prime}\)-disulfonic acid (DIDS, 40 µM, n=5) a HCO\(_3^-\)/Cl\(^-\) transport inhibitor, nor ethacrynic acid (10 µM, n=4), an inhibitor of ATP-dependent, Na\(^+\)-independent Cl\(^-\) transport, blocked the shift in E\(_{Cl^-}\) (not shown).

**The shift in E\(_{Cl^-}\) is independent of extracellular Cl\(^-\)**

The lack of involvement of known plasma membrane Cl\(^-\) transporters indicates that NO is either stimulating an unexamined Cl\(^-\) transport mechanism or releasing Cl\(^-\) from inside the cell. Endosomal compartments are known to maintain relatively high Cl\(^-\) concentrations to offset the membrane potentials generated by inward proton pumping and endosomal acidification (Sonowane and Verkman 2003; Faundez and Hartzell 2004). To determine whether NO was releasing Cl\(^-\) from an internal compartment, external Cl\(^-\) was reduced to match the internal Cl\(^-\) concentration (14.2 mM). NO was applied while cells were held at the reversal potential for Cl\(^-\). Under these conditions, subsequent records collected during pulses of GABA demonstrated that the NO-induced redistribution of Cl\(^-\) persisted in the absence of an electrochemical gradient for chloride
Figure 7. External Cl\textsuperscript{-} is not required for the NO-induced shift in E_{Cl}\textsuperscript{-}. A, A representative cell held at E_{GABA} (0 mV) and pulsed with GABA (horizontal bars) before and after NO application (Cs\textsuperscript{+}-A internal, low Cl\textsuperscript{-} external, ruptured-patch). Increase in leak current following NO application is due to contamination from the NO dependent current (not shown). Scale bars are 200 pA, 100 msec. Time scale applies only to current traces shown (Start-to-start time, 6 sec). B, Top, the voltage protocol for B-i-iii. The first ramp of each pair is for leak subtraction. Ramp pairs were delivered 6 times (Start-to-start time, 10 seconds). Scale bars are 2 sec and 200 msec. B-i) GABA-gated current collected in 0 Cl\textsuperscript{-} solution. Currents from 3 of the 6 voltage ramps are shown and are numbered in order of collection. The outward currents disappear as external Cl\textsuperscript{-} washes out of the bath. The inward current persists but becomes progressively smaller in amplitude. This is likely due to depletion of internal Cl\textsuperscript{-} during the 6 GABA exposures. B-ii, The NO-dependent current (asterisk) indicates the arrival of NO in 0 Cl\textsuperscript{-} solution. B-iii) Currents elicited after NO application in normal Cl\textsuperscript{-} external (gray trace, second ramp pair; black trace, tenth ramp pair). C-E, Control data recorded from a different cell. The voltage protocol shown in B is used but data are shown from the third phase of the experiment only (ramps delivered after switching back to normal external Cl\textsuperscript{-}) C, An NO-induced shift is elicited after NO application in 0 Cl\textsuperscript{-} as in B-iii to show that this cell is responsive to NO. D, In the same cell as C, no change in E_{Cl}\textsuperscript{-} is induced by switching from 0 Cl\textsuperscript{-} to normal Cl\textsuperscript{-} alone. E, Following the same sequence of events, air-exposed NO produces no shift in E_{Cl}\textsuperscript{-}. 
To determine whether external Cl\(^-\) was required at all, NO was also applied in the absence of external Cl\(^-\). For these experiments (Fig. 7 B), control ramps (B-\(i\)) and the NO applications (B-\(ii\)) were conducted in zero Cl\(^-\) external solution. The arrival of NO in zero Cl\(^-\) was marked by the presence of the NO-dependent inward current (asterisk). After switching to normal Cl\(^-\) external solution (TEA-A), so that the reversal potential of the current could be measured, another set of ramps was delivered (B-\(iii\)). Values for the reversal potentials of the GABA-gated currents after NO application (mean shift 26.6 ± 9.9 mV, n=9) indicate that an increase in internal Cl\(^-\) occurred in the absence of external Cl\(^-\). Control experiments were performed in the same manner but without NO application (Fig. 7 D, E). Only slight fluctuations (1-2 mV) in reversal potential resulted from just switching between 0 Cl\(^-\) external and normal external solutions.

The switch back to normal external Cl\(^-\) concentration before measuring the GABA-gated current reversal potentials leaves open the possibility that rapid Cl\(^-\) influx could occur just prior to measuring the reversal potential. To avoid this possibility, we also examined the large NO-induced change in the amplitude of the GABA-gated currents at -70 mV that results from the positive shift in reversal potential. In this way, the effects of NO can be evaluated without re-introducing external Cl\(^-\). In this experiment, both NO and GABA are applied in zero external Cl\(^-\). Substantial increases (2.9 ± 0.7-fold) in the GABA-gated current amplitude were observed in all cells tested (n=5; Fig. 8 A). Because external Cl\(^-\) is absent for both the NO injection and the enhancement of the GABA-gated current, the Cl\(^-\) must be coming from the inside of the cell. Why, in the absence of internal and external Cl\(^-\) (Fig. 3 B), did the NO-induced release of Cl\(^-\) from internal stores not produce an inward GABA-gated current? It is
plausible that under Cl\textsuperscript{-}-free conditions, the Cl\textsuperscript{-} store becomes depleted. Clearly, much remains to be understood about the dynamics of intracellular Cl\textsuperscript{-} fluxes.

**Figure 8. NO promotes release of Cl\textsuperscript{-} from an internal source.**

A. A voltage clamp recording is shown from a representative amacrine cell held at -70 mV (normal internal, TEA external). In the control panel, the external solution was switched to zero Cl\textsuperscript{-} ~90 sec before the pulse of GABA. In this experiment, the rapid perfusion method usually used to apply GABA (Materials and Methods) was used to switch between normal and zero external Cl\textsuperscript{-}. The return to normal external Cl\textsuperscript{-} reduces the size of the current due to the reduction in driving force on Cl\textsuperscript{-}. In the same cell, the protocol was repeated with an NO injection delivered into zero Cl\textsuperscript{-} external 15 seconds before the onset of GABA delivery. The NO-dependent current was observed but is not plotted. The amplitude of the GABA-gated current is enhanced ~3.5-fold, consistent with a substantial positive shift in $E_{Cl}$.

B. GABA-gated currents recorded with high Cl\textsuperscript{-} internal (TEA-B external, predicted $E_{Cl} = 0$ mV) before (black trace) and after (overlapping gray trace) NO.

Aside from the removal of both internal and external Cl\textsuperscript{-}, the only manipulation that blocked the NO-induced shift in Cl\textsuperscript{-} distribution was to raise the internal Cl\textsuperscript{-} concentration to 114 mM. Under these conditions, application of NO produced virtually no shift in the reversal potential of the GABA-gated currents (mean shift = 0.5±0.2 mV, n=5, Fig. 8 B). This result is consistent with internal Cl\textsuperscript{-} release if the 114 mM internal Cl\textsuperscript{-} reduced the gradient for Cl\textsuperscript{-} between an internal Cl\textsuperscript{-} compartment and the cytoplasm.
The NO-induced shift in $E_{Cl^-}$ is not confined to the avian retina

Does the NO-induced shift in Cl$^-$ distribution rely on an amacrine cell-specific mechanism, or is the underlying mechanism more widely expressed? To explore this, we made similar recordings from cultured rat hippocampal neurons. We find that NO also induces a shift in $E_{Cl^-}$ in hippocampal neurons (Fig. 9 A; mean shift 38±19.6 mV, n=6). An inward GABA-independent/NO-dependent current was also observed in hippocampal neurons (Fig. 9 C, asterisk). To determine whether the shift in $E_{Cl^-}$ was also due to internal release of Cl$^-$, we repeated the experiment shown in Fig. 7 B. Removal of extracellular Cl$^-$ during NO application did not inhibit the shift in $E_{Cl^-}$, suggesting that, as for amacrine cells, NO stimulates the release of Cl$^-$ from an internal store in hippocampal neurons (Fig. 9 D).

Figure 9. The NO-induced shift in $E_{Cl^-}$ occurs in rat hippocampal neurons. A. GABA-gated currents recorded from a hippocampal neuron during voltage ramps before (black trace) and after (gray trace) NO application. (Ruptured patch, normal hippocampal external and internal solutions). B-D. Current records elicited by the voltage protocol depicted in Fig. 7B. B. GABA-gated current collected in zero external Cl$^-$. C. The NO-dependent current (asterisk) recorded in zero chloride indicates timing of NO arrival. Scale bar, 2 sec. D. After returning to normal (TEA-H) external solution, a shift in $E_{GABA}$ is revealed. The gray trace is recorded 30 sec after return to normal [Cl$^-$]$_o$ and the black trace is recorded 1 min after return to normal [Cl$^-$]$_o$. Recordings in A-D are from the same cell. Recordings were made in the ruptured-patch configuration with TEA-H or 0Cl$^-$.H external solutions and Cs$^+$-H internal solution.
DISCUSSION

These results indicate that NO can modulate GABAergic signaling through two distinct mechanisms. Prolonged and moderate (~ 100 nM) release of NO from donors enhances GABA-gated currents by modifying receptor activity. Brief pulses of higher concentrations of NO (100’s nM to low µM, NO-bubbled solutions) produce sGC-independent increases in intracellular Cl⁻ and shift $E_{\text{GABA}}$ to more positive potentials. Furthermore, we show that the shift in the Cl⁻ reversal potential occurs at synaptic sites and is sufficient to promote excitation at GABAergic synapses. Finally, our results indicate that the redistribution of Cl⁻ underlying this change results from a release of Cl⁻ from an internal compartment.

The role of NO in the retina

Measurements indicate that the concentration of NO at the cell in NO-bubbled solutions is in the hundreds of nanomolar to low micromolar range. Is this range of concentrations relevant to the levels of NO generated in the retina? NO electrode measurements at the inner retinal surface yield values ranging from 6-15 µM (Donati et al. 1995; Groppe et al. 2003). Consistent with the electrode measurements, a biochemical assay (the Griess method) also shows retinal NO production well into the micromolar range (Heiduschka and Thanos 1998). These intraocular measurements indicate that NO concentrations can be substantial and that the doses of NO used in our experiments are within the physiological range.

Recently, NO electrode measurements have been made near the surface of an individual cell in the ganglion cell layer of the turtle retina (Eldred and Blute 2005). An NO concentration of about 200 nM was detected. It is important to note, however, that
imaging of NMDA-stimulated NO production in the same retina has demonstrated that
the NO signals generated are often highly localized to individual cells and even discrete
boutons in the inner synaptic layer (Blute et al. 2000). This observation suggests that
some of the the downstream effects of NO signaling occur primarily in nNOS-expressing
cells and their immediate synaptic partners, where NO concentrations would be higher.
How might the NO-induced changes we show for cultured amacrine cells affect
GABAergic signaling between amacrine cells in the inner retina? The diversity of
synaptic partners and complex synaptic arrangements of amacrine cells in the IPL
(Dowling and Boycott 1965; Kolb 1997; Hartveit 1999; Marc and Liu 2000) complicate
this issue. The cartoon in Figure 10 depicts a simplified subset of interactions in the
inner retina. The cell on the left is a GABAergic or glycinergic, nNOS-expressing
amacrine cell that receives a mixture of excitatory (glutamatergic, from bipolar cells) and
inhibitory (GABA- and/or glycinergic, from other amacrine cells) inputs. The net effect
of these inputs is to determine the strength of the inhibitory output from the cell onto its
postsynaptic partners (ganglion cells, bipolar cells, and/or amacrine cells). If the cell is
exposed to a relatively high concentration of NO (presumably via its own nNOS activity),
the distribution of chloride shifts in that amacrine cell so the balance of its input becomes
more excitatory and the inhibitory output of this cell is enhanced. Consistent with this
proposal, Wang et al. (2003) demonstrate an NO-dependent suppression of ganglion cell
light responses that is due to alterations in presynaptic (probably amacrine cell) input.
This observation would be consistent with an NO-dependent shift in the amacrine cell
$E_{Cl^-}$ that results in an enhancement of inhibitory output onto ganglion cells.
Figure 10. Model for NO effects on amacrine cell signaling. An nNOS-expressing GABA- or glycine-ergic amacrine cell receiving both inhibitory and excitatory input generates a moderate inhibitory output (left). After NO, $E_{Cl^-}$ shifts positive (darker shading), all inputs become excitatory, and inhibitory output from the amacrine cell is enhanced. The cells depicted are highly simplified in that amacrine cell synaptic inputs and outputs are not typically segregated.

A potential source of internal Cl$^-$

Our results indicate that the NO-induced redistribution of Cl$^-$ is due to Cl$^-$ release from inside the cell. Endosomal compartments are a potential source of internal Cl$^-$. Cl$^-$ is thought to enter these compartments as a counter ion for protons being pumped in by vacuolar proton pumps (Sonawane and Verkman 2003). Movement of Cl$^-$ across endosomal membranes is thought to be mediated by the CLC family of Cl$^-$ transport proteins. CIC 3-7 are found on intracellular membranes (for review see Jentsch et al., 2002; Faundez and Hartzell 2004). Of these, CIC3 may be the most relevant because it is highly expressed in the brain and has been shown to be expressed on endosomes, including synaptic vesicles. Interestingly, knockouts of the CIC3 gene resulted in marked tissue degeneration specifically in the hippocampus and the retina (Stobrawa et al. 2001).
Although physiological evidence for a role for CLC transport proteins in the NO-induced shift in $E_{Cl^{-}}$ awaits further experimentation, we have found that a polyclonal antibody raised against a conserved peptide from ClC3 gives an intense and punctuate labeling pattern that appears to be located intracellularly (McMains and Gleason, unpublished observations). It may be that the efflux of Cl$^{-}$ from endosomes via ClC3 contributes to the NO-induced shifts in $E_{GABA}$ and $E_{glycine}$ and the transitions between inhibition and excitation.

Interestingly, NO has been shown to reversibly inhibit the vacuolar proton pump through S-nitrosylation (Forgac 1999). Although the mechanism by which NO stimulates Cl$^{-}$ efflux is not yet known, given the established relationship between proton pumping and Cl$^{-}$ movement across endosomal membranes, it is plausible that proton flux is somehow involved. However the Cl$^{-}$ efflux is achieved, the demonstration that it does occur, and that it may be a broadly expressed mechanism, is sure to impact our view of GABA and glycine-dependent synaptic signaling in the CNS.
ACKNOWLEDGEMENTS:

We would like to thank Martin Wilson for valuable discussions about this work, Rustin Moore and Frank Garza for use of their nitric oxide electrode, and to Huangen Ding for his generosity in providing us with nitric oxide-bubbled solutions. This work was supported by a Louisiana State Board of Regents Fellowship and Sigma Xi Grant in Aid of Research (to E. M.) and NIH Grant R01 EY12204 (to E.G.).
