Abstract

Information processing in the cerebral cortex involves interactions among distributed areas. Anatomical connectivity suggests that certain areas form local hierarchical relations such as within the visual system. Other connectivity patterns, particularly among association areas, suggest the presence of large-scale circuits without clear hierarchical relations. Here the organization of networks in the human cerebrum was explored using resting-state functional connectivity MRI (fcMRI). Data from 1000 subjects were registered using surface-based alignment. A clustering approach was employed to identify and replicate networks of functionally coupled regions across the cerebral cortex. The results revealed local networks confined to sensory and motor cortices as well as distributed networks of association regions. Within the sensory and motor cortices, functional connectivity followed topographic representations across adjacent areas. In association cortex, the connectivity patterns often showed abrupt transitions between network boundaries. Focused analyses were performed to better understand properties of network connectivity. A canonical sensory-motor pathway involving V1, putative MT+, LIP and FEF was analyzed to explore how interactions might arise within and between networks. Results showed that adjacent regions of the MT+ complex demonstrate differential connectivity consistent with a hierarchical pathway that spans networks. The functional connectivity of parietal and prefrontal association cortices was next explored. Distinct connectivity profiles of neighboring regions suggest they participate in distributed networks that, while showing evidence for interactions, are embedded within largely parallel, interdigitated circuits. We conclude by discussing the organization of these large-scale cerebral networks in relation to monkey anatomy and their potential evolutionary expansion in humans to support cognition.
Introduction

Complex behaviors are subserved by distributed systems of brain areas (Felleman and Van Essen 1991; Goldman-Rakic 1988; Mesulam 1990). The organization of these systems can be studied in non-human animals using invasive techniques including histology, anatomic tract tracing, electrophysiology, and lesion methods. The organization of brain systems in the human has been inferred by comparing cytoarchitectonically-defined homologies between species, and by noting similarities in neuropsychological deficits following accidental brain injury to deficits present in animal ablation studies. General agreement has emerged from these comparisons that the basic organization of brain systems is similar across mammalian species. However, there is also evidence that the human cerebral cortex, particularly association cortex, is not simply a scaled version of other species.

The German anatomist Korbinian Brodmann (1909) first emphasized that areas comprising the human inferior parietal lobule do not have clear homologues in the monkey -- an observation that continues to motivate contemporary debates (Orban et al. 2004). Gross differences are also observed in the human brain when it is compared to our evolutionarily closest relatives. For example, the human brain is triple the size of modern great apes but motor and visual cortices are about the same absolute size (Blinkov and Glezer 1968; Frahm et al. 1984). This observation suggests that expansion of the human cerebrum disproportionately involves areas beyond those subserving basic sensory and motor functions. In a recent analysis of cortical expansion based on 23 homologous areas between the macaque and human, Van Essen and colleagues noted that the greatest growth occurs in regions distributed across frontal, parietal, and temporal association cortices (Van Essen and Dierker 2007; Hill et al. 2010). Preuss (2004) came to a similar conclusion in a detailed review of comparative anatomy. Thus, in addition to expecting the human brain to show broadly similar organizational properties with other well-studied species, expansion and perhaps elaboration of association networks is also expected.

In this paper we report results of a comprehensive analysis of networks within the human cerebral cortex using intrinsic functional connectivity MRI (fcMRI). The analysis was based on 1000 young adults who contributed uniformly collected MRI data. The data
were brought into a common surface coordinate system to help preserve the surface
topology of the cortical mantle. Analyses were motivated by two goals. First, we sought
to provide reference maps that are a current best estimate of the organization of the
human cerebral cortex as measured by functional connectivity. Second, we wanted to
better understand how patterns of functional connectivity might give rise to the
organizational properties that underlie distributed brain systems. Particular focus was
placed on parietal and frontal association cortices. The foundations for the present work
come from traditional anatomical studies of cortical organization.

Organizational properties of the cerebral cortex in the non-human primate

Distributed brain systems are organized to facilitate both serial and parallel
processing (Felleman and Van Essen 1991; Mesulam 1998). The concept of serial
hierarchies is embedded within early ideas about brain organization. For example,
William James (1890) proposed that principles governing the reflex arc extend to the
cerebral hemispheres. He hypothesized that excitement of sensory systems propagates
upwards from lower to higher cerebral centers governing “ideas”, then to centers
producing (or inhibiting) movements. Hubel and Wiesel (1962) formally proposed the
concept of serial processing across a hierarchy in cat visual cortex based on their
observations of increasingly complex receptive field properties from the lateral geniculate
nucleus (LGN) to the simple and complex cells of V1. Based on studies of corticocortical
connections in the macaque, Pandya and Kuypers (1969) and Jones and Powell (1970)
suggested that hierarchical processing across sensory systems converges on transmodal
association areas.

The discovery of widespread connections among multiple cortical areas, as well
as extensive feedback projections from higher to lower sensory areas, suggested strictly
serial processing is not the only organizational scheme in the cerebral cortex. Instead, it
was proposed that hierarchical processing exists in a distributed fashion that can be
inferred from the laminar distribution of anatomical connectivity (Friedman 1983;
Maunsell and Van Essen 1983; Rockland and Pandya 1979). The comprehensive meta-
analyses of corticocortical connections in the macaque monkey by Felleman and Van
Essen (1991) provided strong evidence that unimodal and heteromodal areas in both the
visual and somatomotor systems are organized into separate distributed hierarchies (also see Ungerleider and Desimone 1986; Van Essen et al. 1992). Some projections between areas are organized as feedforward (ascending) projections, others as feedback (descending) projections, and still others as lateral projections. For example, consistent with serial processing, the primary visual area (V1) sends forward connections to and receives feedback connections from V2 in a topographic fashion that connects the corresponding receptive field representation in each area. In contrast to strictly serial processing, these unimodal sensory cortical areas (V1 and V2) both project to higher sensory areas. Lateral projections between areas are also common (e.g., CIT and STPp).

It becomes considerably more difficult to make inferences about the organization of circuits involving association cortex. Historically, of the four criteria – function, cytoarchitecture, connectivity and topography – used to define cortical areas and thereby constrain models of organization, topography (e.g., retinotopy) and function are difficult to discern in heteromodal association areas. Cytoarchitecture and connectivity thus become especially valuable for inferring brain circuit organization beyond the sensory and motor systems. However, as noted by Felleman and Van Essen (1991), the number of violated constraints to hierarchical connectivity increases in the progression from early sensory cortex up to association cortex (red lines near the top of the visual hierarchy in Fig. 4 of Felleman and Van Essen 1991).

This raises the interesting possibility that the association areas may not follow as rigid a hierarchical organization as canonical sensory and motor areas. Violations of strict hierarchical arrangements are apparent in the visual system as noted above, but violations and alternative connectivity patterns become common in association areas. For example, paired tracer injections in association areas 7a and 46 lead to interdigitating columnar patterns of terminations in some areas and complementary (feedforward and feedback) patterns in other areas (Selemon and Goldman-Rakic 1988).

While recognizing that convergence and integration of pathways occurs in the association cortex, Goldman-Rakic (1988) emphasized that primate association cortex is organized into parallel distributed networks (see also Mesulam 1981). There are two key features to her proposed organization that depart from hierarchical organizational models. First, each distributed network consists of association areas spanning frontal, parietal,
temporal and cingulate cortices. Networks are densely interconnected, such that two areas
in the parietal and frontal cortices belonging to the same network are not just
anatomically connected to each other, but they are also both connected with other
components of the same network (Selemon and Goldman-Rakic 1988). Second, multiple
distributed networks exist adjacent to each other: adjacent areas in the parietal cortex
belonging to separate networks are differentially connected to adjacent areas of
corresponding networks in the frontal, temporal and cingulate cortices (Cavada and
Goldman-Rakic 1989a; 1989b).

The possibility of parallel distributed circuits will be an important consideration
in our analysis of fcMRI networks in the human, particularly within association cortices.
An intriguing possibility is that the majority of the human cerebral cortex involves
multiple parallel circuits that are interdigitated throughout association cortex, such that
each cortical lobe contains components of multiple association networks. That is, the
expansion of the cerebral association cortex in humans relative to the macaque may
preferentially involve networks organized in the form outlined by Goldman-Rakic (1988)
and anticipated by others (e.g., Mesulam 1981). To explore this possibility, analyses will
focus both on evidence for hierarchical relations across regions as well as evidence for
distributed networks that are interdigitated throughout association cortex.

Insights into the organization of the cerebral cortex revealed through neuroimaging
Noninvasive neuroimaging methods including positron emission tomography
(PET; Raichle 1987) and functional MRI (fMRI; Kwong et al. 1992; Ogawa et al. 1992)
allow functional response properties to be measured in the human cerebral cortex. The
measures are indirect, reflecting blood flow and oxygenation changes that are coupled to
neural activity through incompletely understood mechanisms (Logothetis 2008), and the
methods are presently limited to a spatial resolution of a few mm (e.g., Engel et al. 1997).
Neuroimaging approaches have nonetheless been extremely valuable for providing
insights into cortical organization. In some cases it has been possible to directly map the
topography within (and borders between) cortical areas (Engel et al. 1994; Sereno et al.
1995). More generally, differential response properties between regions are the source of
information about cortical mapping. For example, the increase in the complexity of
receptive field properties measured from primary to secondary sensory areas in visual
(Wandell et al. 2007), somatosensory (Iwamura 1998), and auditory (Wessinger et al.
2001) cortices suggest that serial hierarchical processing exists in human sensory cortex.

Neuroimaging studies of a wide range of cognitive tasks reveal simultaneous
activation in multiple regions in the parietal, frontal, temporal and cingulate cortices,
suggesting distributed systems of brain areas are involved in cognition. However, it is
difficult to assess the organization of these distributed systems based solely on task
activity because these cognitive tasks likely tap into multiple, overlapping processes,
some of which reflect the operation of distributed systems and others which reflect
distinct processing demands of the tasks (see Mesulam 1990 and Posner et al. 1988 for
relevant discussion). For these reasons, methods that can measure connectivity may
provide novel insights into the organization of distributed brain systems.

Functional connectivity and diffusion MRI provide tools to explore cortical organization
Diffusion MRI (dMRI) and fcMRI have recently emerged as promising tools for
mapping the connectivity of the human brain, each with distinct strengths and
weaknesses. dMRI measures the diffusion of water thus allowing direct non-invasive
mapping of white matter pathways (Basser et al. 1994). However, dMRI is presently
limited to resolving major fiber tracts. By contrast, fcMRI measures intrinsic functional
correlations between brain regions (Biswal et al. 1995) and is sensitive to coupling
between distributed as well as adjacent brain areas (e.g., see Sepulcre et al. 2010 for
discussion). While not a direct measure of anatomical connectivity, the functional
couplings detected by fcMRI are sufficiently constrained by anatomy to provide insights
into properties of circuit organization (for reviews, see Fox and Raichle 2007; Van Dijk
et al. 2010). When describing these correlations, we use the term functional connectivity
as coined by Karl Friston (1994) to denote “temporal correlations between remote
neurophysiological events” for which the causal relation is undetermined.

There are important limitations of fcMRI including sensitivity to indirect
anatomical connectivity and functional coupling that changes in response to recent
experience and the current task being engaged (Buckner 2010). For these reasons, some
discussions of fcMRI have emphasized that intrinsic activity measured by fcMRI reflects
the prior history of activity through brain systems and not simply static anatomic
connectivity (Power et al. 2010). fcMRI also does not presently provide information
about whether connections are feedforward (ascending) or feedback (descending). These
limitations constrain how analyses are conducted and results can be interpreted.

Directly relevant to the present study, prior investigations using fcMRI provide
estimates of large-scale cortical networks that have generally (but not in all details)
converged across a variety of analytic approaches, including seed-based fcMRI (Biswal
et al. 1995), independent component analysis (Beckmann and Smith 2004; Smith et al.
2009), clustering (Bellec et al. 2010; Golland et al. 2007) and graph theory (Dosenbach et
al. 2007). Because of uncertainties regarding their relation to underlying anatomic brain
systems, networks identified using fcMRI have often been labeled based on their
relations to task-based functional networks. Some of these networks, such as the default
network (Greicius et al. 2003) and dorsal attention system (Fox et al. 2006), have been
proposed to be related to anatomical tracing and task-based fMRI in the macaque
(Buckner et al. 2008; Saleem et al. 2008; Vincent et al. 2007).

Motivated by the usefulness of connectivity in establishing the organization of the
cerebral cortex in non-human primates, this study analyzed fcMRI data from 1000
subjects with two main goals. First, the analyses sought to provide reference maps that
are a current best estimate of the organization of human cortical networks as measured by
functional connectivity. Second, by using the power of a large data sample to
quantitatively measure functional connectivity strength among many regions, the study
explored the patterns of corticocortical functional coupling that give rise to these
networks.

Methods

Overview

The present study explored the organization of large-scale distributed networks in
the human cerebral cortex using resting-state fcMRI. The main analyses were based on a
core dataset of 1000 healthy, young adults whose fMRI data were acquired using the
same MRI sequence on the same hardware (3 Tesla field strength, 12-channel receive coil
array). For several analyses the data were divided into Discovery (n = 500) and Replication (n = 500) data samples to test for reliability and for unbiased quantification of functional connectivity patterns. Additional supplementary datasets were used to address specific questions that arose during analysis. A first supplementary fMRI dataset (n = 16) contrasted different passive tasks engaged during resting-state functional data acquisition. A second supplementary fMRI dataset (n = 4) consisted of data acquired during visual stimulation optimized to define retinotopic boundaries of early visual areas (Hinds et al. 2009; Polimeni et al. 2005). A final supplementary dataset used human histological data to define a range of cytoarchitectonic areas including human V1 (Amunts et al. 2000, Fischl et al. 2008) and the putative homologue to macaque MT+ (Malikovic et al. 2007, Yeo et al. 2010b). All data (fMRI and histological) were brought into a common surface coordinate system based on the cortical surface as reconstructed from each participant’s structural anatomy. Data analyses began by examining broad properties of cortical network organization and progressed to quantify the detailed patterns of functional connectivity within and between networks.

In the first set of analyses, a clustering algorithm was used to parcellate the cerebral cortex into networks of functionally coupled regions. Parcellations were examined for a coarse solution that organized the cortex into 7 networks as well as a finer solution that identified 17 networks. As the results will reveal, the estimated networks were consistent across the Discovery and Replication data samples and confirmed by region-based fcMRI analyses. The full dataset was used to construct a best-estimate parcellation of the human cerebral cortex to serve as a reference for future studies.

The second set of analyses explored the coupling of regions that fell within sensory and motor pathways. Since these areas are relatively well understood in both humans and macaques, they provide the opportunity to evaluate the utility and limitations of functional connectivity methods. Analyses examined quantitative coupling properties between individual regions that were within the same network as well as coupling properties between networks focusing on a sensory-motor pathway that is the putative homologue of the well-studied system in the monkey involving MT+, parietal regions at or near LIP, and premotor regions at or near FEF.
The final set of analyses characterized the organization of distributed networks in higher-order association cortex. The connectivity patterns of regions within frontal and parietal association cortices were quantified. These analyses involved constructing a series of small seed regions across frontal and parietal cortices and examining functional connectivity strength to multiple regions distributed throughout the cerebral cortex, allowing the ‘fingerprint’ of functional coupling to be identified for each region. For these analyses, regions were always defined in the Discovery data sample or some other source, such as histology, and functional connectivity quantified in the independent Replication data sample.

Participants

Paid participants were clinically healthy, native English speaking young adults with normal or corrected-to-normal vision (ages 18 to 35). Subjects were excluded if their fMRI signal-to-noise ratio (SNR) was low (< 100; see below), artifacts were detected in the MR data, their self-reported health information indicated the presence of any prior neurological or psychiatric condition, or they were taking any psychoactive medications. The core dataset consisted of 1000 individuals imaged during eyes open rest (EOR) and was divided into two independent samples (each n = 500; labeled the Discovery and Replication samples). Age and gender were matched for the Discovery (mean age = 21.3 yr, 42.6% male) and Replication (mean age = 21.3 yr, 42.8% male) datasets. These data are new data presented for the first time in this study and were acquired as part of a collaborative effort across multiple local laboratories all acquiring data on matched MRI scanners (at Harvard and at the Massachusetts General Hospital). Participants provided written informed consent in accordance with guidelines set by institutional review boards of Harvard University or Partners Healthcare.

Two smaller supplementary datasets were also analyzed. The Task Effect dataset (n = 16, mean age = 21.1 yr, 25.0% male) consisted of fMRI data collected under different passive conditions (eyes closed rest, ECR; EOR; and fixation, FIX) and was analyzed previously (Van Dijk et al. 2010). The Visuotopic dataset (n = 4; mean age = 34.5 yr, 100% male) consisted of previously published visuotopic data (Hinds et al. 2009; Polimeni et al. 2005).
**MRI data acquisition**

All data were collected on matched 3T Tim Trio scanners (Siemens, Erlangen, Germany) using a 12-channel phased-array head coil except for the Visuotopic dataset, which was acquired on a custom-built four-channel phased-array surface coil. A software upgrade (VB15 to VB17) occurred on all scanners during the study. Validation studies that acquired structural and functional data on the same individuals before and after the upgrade could not detect an effect of the upgrade. The functional imaging data were acquired using a gradient-echo echo-planar imaging (EPI) sequence sensitive to blood oxygenation level-dependent (BOLD) contrast. Whole-brain coverage including the entire cerebellum was achieved with slices aligned to the anterior-commissure posterior-commissure (AC-PC) plane using an automated alignment procedure ensuring consistency between subjects (van der Kouwe et al. 2005). Structural data included a high-resolution multi-echo T1-weighted magnetization-prepared gradient-echo image (multi-echo MP-RAGE; van der Kouwe et al. 2008).

For the core dataset, subjects were instructed to remain still, stay awake and to keep their eyes open. EPI parameters were as follows: TR = 3000 ms, TE = 30 ms, FA = 85°, 3 x 3 x 3 mm voxels, FOV = 216 and 47 axial slices collected with interleaved acquisition and no gap between slices. Each functional run lasted 6.2 min (124 time points). One or two runs were acquired per subject (average of 1.7 runs). Parameters for the structural scan (multi-echo MP-RAGE; van der Kouwe et al. 2008) were as follows: TR = 2200 ms, TI = 1100 ms, TE=1.54 ms for image 1 to 7.01 ms for image 4, FA = 7°, 1.2 x 1.2 x 1.2 mm voxels and FOV = 230. The multi-echo MP-RAGE allows increased contrast through weighted-averaging of the four derived images.

For the Task Effect dataset, subjects were instructed to remain still with their eyes open (EOR; two runs), eyes closed (ECR; two runs) or to passively fixate a centrally presented crosshair (FIX; two runs). For details see Van Dijk et al (2010). The order of rest conditions was counterbalanced across subjects. EPI parameters were as follows: TR = 3000 ms; TE = 30 ms; FA = 90°; 3 x 3 x 3 mm voxels; FOV = 288 and 43 slices collected with interleaved acquisition and no gap between slices. Each functional run lasted 7.15 min (143 time points). Parameters for structural scans (MP-RAGE) were as
follows: TR = 2530 ms, TI = 1100 ms, TE = 3.44 ms, FA = 7º, 1 x 1 x 1 mm voxels and FOV = 256.

The Visuotopic dataset was collected using a custom-built four-channel phased-array surface coil placed at the back of the head. During each functional run, subjects were presented with one of four visual stimuli: a clockwise rotating wedge, a counterclockwise rotating wedge, an expanding ring, or a contracting ring (DeYoe et al. 1996; Engel et al. 1994; Sereno et al. 1995). Because the four-channel surface coil provided only partial brain coverage, structural data for these four subjects were collected separately on a 1.5T Allegra scanner (Siemens, Erlangen, Germany). Further details of the acquisition and data processing protocol can be found elsewhere (Hinds et al. 2009; Polimeni et al. 2005).

Except where noted, the description of data processing and analysis below applies to the whole-brain data (the core dataset of 1000 subjects and the Task Effect dataset) and not the Visuotopic data.

Functional MRI data preprocessing

The fMRI data were preprocessed with a series of steps common to fMRI analyses. Preprocessing involved (1) discarding the first four volumes of each run to allow for T1-equilibration effects, (2) compensating for slice-acquisition-dependent time shifts per volume with SPM2 (Wellcome Department of Cognitive Neurology, London, UK), and (3) correcting for head motion using rigid body translation and rotation with the FSL package (Jenkinson et al. 2002; Smith et al. 2004).

The data underwent further processing using procedures adapted from Biswal et al. (1995) and optimized for fcMRI analysis (Fox et al. 2005; Van Dijk et al. 2010; Vincent et al. 2006). Briefly, a low-pass temporal filter removed constant offsets and linear trends over each run while retaining frequencies below 0.08 Hz. Sources of spurious variance, along with their temporal derivatives, were removed through linear regression including: (1) six parameters obtained by correction for rigid body head motion, (2) the signal averaged over the whole brain, (3) the signal averaged over the ventricles, and (4) the signal averaged over the deep cerebral white matter. This regression procedure minimized signal contributions of non-neuronal origin including
respiration-induced signal fluctuations (Van Dijk et al. 2010). Unlike previously established fcMRI preprocessing procedures, no spatial smoothing of the resting-state data occurred up to this point of the preprocessing stream.

Structural MRI data preprocessing and functional-structural data alignment

The structural data were processed using the FreeSurfer software (http://surfer.nmr.mgh.harvard.edu) version 4.5.0 software package. The FreeSurfer software package constitutes a suite of automated algorithms for reconstructing accurate surface mesh representations of the cortex from individual subjects’ T1 images (Fig. 1B-C) and the overlay of fMRI on the surfaces for group analysis (Fig. 1D-E). Briefly, the cortical surface extraction process (Fig. 1B-C) involved (1) correcting for intensity variations due to MR inhomogeneities (Dale et al. 1999), (2) removing extra-cerebral voxels through “skull-stripping” (Ségonne et al. 2004), (3) segmenting cortical gray and white matter voxels based on the intensity difference and geometric structure of the gray-white interface (Dale et al. 1999), (4) computing cutting planes to disconnect the two hemispheres and subcortical structures (Dale et al. 1999), (5) filling the interior holes of the segmentation using a connected-component analysis (Dale et al. 1999), (6) tessellating a triangular mesh over the gray-white boundary of each hemispheric volume and deforming the mesh to produce a smooth representation of the gray/white interface and pial surface (Dale et al. 1999), and (7) correcting topological defects in the surface so that the mesh achieves a spherical topology (Fischl et al. 2001; Ségonne et al. 2007).

After segmentation of the cortical surface, spatial correspondences among the subjects’ cortical folding patterns were established via the use of a spherical coordinate system (Fig. 1D-E). Briefly, the process involved (1) inflating each subject’s surface mesh into a sphere while minimizing geometric distortion of the original cortical surface.
as measured by geodesic distances among surface vertices and ensuring the inflation
constituted a one-to-one mapping, and (2) computing a smooth, invertible deformation of
the resulting spherical mesh to a common spherical coordinate system that aligned the
cortical folding patterns across subjects (Fischl et al. 1999a; Fischl et al. 1999b).

Once the common spherical coordinate system was established, the structural and
functional images were aligned (Fig. 1A-B) using boundary-based registration (Greve
and Fischl 2009) that is provided as part of FreeSurfer’s companion package, FsFast
(http://surfer.nmr.mgh.harvard.edu/fswiki/FsFast). The preprocessed resting state fMRI
data were then propagated to the common spherical coordinate system via sampling from
the middle of the cortical ribbon in a single interpolation step (Fig. 1A-E). The choice of
sampling fMRI data from the middle of the cortical ribbon was motivated by the desire to
reduce the blurring of fMRI signal across sulci or gyri and also by a recent study on the
point-spread function of fMRI (Polimeni et al. 2010). The study showed that large
draining vessels on the pial surface increased BOLD signal close to the pial surface but
reduced spatial specificity of the hemodynamic response. Sampling fMRI data from the
middle of the cortical ribbon therefore represented a trade-off between spatial specificity
and signal sensitivity. Since our fMRI voxels were relatively large (3mm), we were not as
concerned about laminar bias in the functional connectivity analysis.

The cerebral cortex is a thin sheet, with common organizational features along its
radial axis. Along the dimensions parallel to this sheet is a mosaic of cortical areas that
differ in architecture, connectivity, function, and/or topographic organization (Felleman
and Van Essen 1991; Kaas 1987). The spherical representation of the cortex therefore
affords a more accurate alignment of the cortical folding pattern and has the consequence
of improving cytoarchitectural (Fischl et al. 2008; Hinds et al. 2008; Yeo et al. 2010a)
and functional (Fischl et al. 1999b; Van Essen 2005) correspondences across subjects
compared with 3D volumetric registration even though cortical folds do not completely
predict cytoarchitecture or function (Rajkowska and Goldman-Rakic 1995; Thirion et al.
2007; Yeo et al. 2010b). The acquisition resolution and inherent limitations of the BOLD
signal also provided restrictions on achievable resolution.
A 6mm FWHM (full width at half maximum) smoothing kernel was applied to the fMRI data in the surface space and the data were downsampled to a 4mm mesh. Smoothing after the fMRI data were projected onto the surface helped to minimize the blurring of fMRI signal across sulci or gyri. Since our algorithms are not perfectly accurate, any registration or segmentation errors will likely cause blurring of fMRI signal across sulci or gyri. Consequently, we did not expect to eliminate the blurring issues completely, which is important to keep in mind when interpreting the results. The steps taken could only minimize the problem.

The processing of the Visuotopic dataset was broadly similar except that older versions of FreeSurfer and FsFast were used for the processing and so manual interventions were required to correct the T2* to T1 registration. Details of the processing can be found elsewhere (Hinds et al. 2009; Polimeni et al. 2005).

Quality control

Visual inspection of the registered data suggested that accurate representation of the cortical surface was extracted for each subject and that structural and functional image registration was successful. Figure 2 shows the results of cortical surface extraction from the T1 images and T2* to T1 registration of 3 randomly chosen subjects. These examples represent typical subjects. Note that functional data distortion remains in areas prone to susceptibility artifacts including anterior prefrontal regions, regions near lateral temporal cortex, and orbital frontal cortex.

------------------------------------------------------------------

Insert Figure 2 About here

------------------------------------------------------------------

1 It is not possible to generate a high resolution uniform mesh on the sphere. However, one can work with approximately uniform spherical meshes at different spatial resolutions by starting with a regular icosahedron mesh consisting of 20 equal faces and 12 vertices and iteratively subdividing each mesh triangle into four smaller triangles. Here each cortical hemisphere is represented by a subdivided icosahedron mesh with 20480 faces and 10242 vertices, where neighboring pairs of vertices are on average 3.8 mm apart (max = 4.1 mm, min = 3.4 mm).
Visualization

While all subsequent analyses were performed in FreeSurfer surface space, for the purpose of visualization, all maps were transformed and displayed on the inflated PALS cortical surfaces using Caret software (Van Essen 2004; 2005; Van Essen and Dierker 2007). In addition, this study also transformed and visualized the estimated networks in FMRIB Software Library (FSL) MNI152 space (Smith et al. 2004). The mapping between FSL MNI152 volumetric space and FreeSurfer surface space is detailed in our companion study (Buckner et al. submitted).

Signal-to-noise ratio (SNR) maps

Signal loss and distortion (susceptibility artifacts) occur as a result of magnetic field inhomogeneities. Field inhomogeneities are particularly pronounced in regions where the brain is adjacent to air, causing signal loss and distortion in T2*-dependent (BOLD) images (Ojemann et al. 1997). To estimate the effects of susceptibility artifacts in the present data, the signal-to-noise ratio (SNR) of the motion corrected fMRI time series was computed for each voxel in subjects’ native volumetric space by averaging the signal intensity across the whole run and dividing it by the standard deviation over time. SNR was also used as exclusionary criteria. If the SNR for the whole brain (mean SNR over all voxels within the brain mask) was <100 for an fMRI run, the subject was excluded. Thus, all 1000 subjects contributed data with SNR > 100 for each fMRI run. For subjects with two runs, the SNR was averaged across the runs. The SNR was then projected to FreeSurfer surface space, averaged across the 1000 subjects from the core dataset, and displayed in Caret PALS space (Fig. 3). As expected, low SNR is present in the anterior portion of the inferior and medial temporal lobe, as well as in the orbital frontal cortex. There is also clear spatial variation in the SNR across the cortical mantle, which is important to keep in mind when interpreting the results, such as the absence of a cortical region of low SNR from a network.
Clustering

We applied a clustering approach to define the boundaries of functionally distinct cortical regions and their relations to regions distributed throughout the cerebral cortex (forming networks). Distinguishing neighboring cortical regions by their pattern of connectivity has a long history in both non-human primate (e.g., Cavada and Goldman-Rakic 1989a; Goldman-Rakic 1988; Passingham et al. 2002) and human (e.g., Cohen et al. 2008; Johansen-Berg et al. 2004; Nelson et al. 2010) research. Here we began our analyses by defining cortical networks to be sets of cortical regions with similar profiles of corticocortical functional connectivity. The idea follows the empirical finding that in primates, regions of association cortex that are anatomically connected tend to have similar patterns of anatomical connectivity to other cortical and subcortical regions, thus forming a densely connected distributed network (Goldman-Rakic 1988). Note that this assumption about the organizational properties of corticocortical connectivity is probably neither a characteristic of all cortical regions nor a full characterization of the connectivity pattern of any cortical region. As will be shown, the procedure identified functionally coupled networks that could be verified with seed-based regional analyses that made no assumptions about the connectivity patterns.

For this initial analysis, we defined the connectivity profile of a cortical region to be its functional coupling to 1175 region of interest (ROI) vertices. The 1175 ROI vertices were uniformly sampled in FreeSurfer surface space (shown in Caret PALS space in Fig. 4) and consisted of single vertices spaced about 16mm apart. For each subject, we computed the Pearson’s product moment correlation between the fMRI time series at each spatial location (18715 vertices) and the 1175 ROI vertices. Each spatial location is therefore characterized by its functional coupling to the 1175 ROI vertices. We binarized the 18715 x 1175 matrix of correlations for each subject by keeping the top 10% of the correlations and averaged the binarized matrices independently across each group of 500 subjects in the Discovery and Replication samples. If a subject had two
runs, we averaged the correlation matrices across the two runs before binarization. As will be shown in the results, binarization of the correlation matrix leads to significantly better clustering results, although the algorithm appears robust to the particular choice of threshold. Visual inspection of the connectivity profiles (not shown) suggested that the 1175 ROI vertices were sufficiently dense to capture spatial variation in corticocortical connectivity given the limits of our acquisition procedures.

A clustering algorithm was then applied separately to the Discovery and Replication samples to estimate networks of cortical regions with similar connectivity profiles. The two independent datasets thus allowed exploration of the reliability of estimated networks. The idea behind clustering can be illustrated with a toy example. Figure 5A shows hypothetical points scattered in a structured fashion on a two-dimensional canvas. Clustering aims to recover this structure by dividing the points into different groups so that points within a group are physically close, such as shown in Figure 5B.

The clustering algorithm employed in this study modeled the data with a von Mises-Fisher distribution (Lashkari et al. 2010). More specifically, the data were modeled as 18715 points on an 1174-dimensional unit hypersphere embedded in an 1175-dimensional Euclidean space, where distances between points were measured by their geodesic distance on the hypersphere. Like the toy example, clustering aims to group vertices that are close together in this non-Euclidean canvas (i.e., have similar connectivity profiles) into the same cluster or network. Measuring distances between points by their geodesic distance is equivalent to defining the similarity between two correlation profiles to be the correlation between the correlation profiles. By using correlation as a measure of similarity, differences in correlation strength were normalized among points so that regions are clustered together based on their connectivity profiles.
(rather than their strengths of connectivity). In theory, this should mitigate the effects of spatial variation in SNR (Fig. 3).

The algorithm operated by randomly assigning the 18715 points to different groups and then iteratively reassigning the group memberships of points to maximize the agreement of connectivity profiles among points of the same group. More details of the clustering algorithm can be found elsewhere (Lashkari et al. 2010).

Stability analysis

A drawback of most clustering approaches is that one must choose the number of clusters a priori. In this instance, the question is how many clusters – cerebral networks – are needed to correctly parcellate the cortex? We do not have an answer to this question or know if there is a single correct answer given that the cerebral cortex possesses complex patterns of diverging and converging connections among areas. As such, none of our conclusions will depend on a strong assumption that there is a single correct solution to parcellating the cortex. Nonetheless, we sought a principled approach to identify parcellation solutions that captured significant portions of the correlation structure among cortical regions.

One popular method for estimating the number of clusters is by analyzing the stability of the clustering algorithm (Ben-Hur et al. 2002; Lange et al. 2004; also see Fig. 5). We employed two variations of the stability analysis on the full set of 1000 subjects. Both variations estimated the same numbers of clusters. The first variation involved (repeatedly and randomly) dividing the ROIs into two groups and measuring the reproducibility of the clustering algorithm’s results when applied separately to the two groups of ROIs. The second variation involved (repeatedly and randomly) dividing the 18715 vertices into two groups and applying the clustering algorithm separately to the two groups of vertices. The model parameters learned from clustering one group of
vertices was then used to predict the clustering results of the second group of vertices. The agreement between the prediction and clustering results of the second group measured the generalization power of the clustering results (Fig. 6). Further details of the stability analysis can be found elsewhere (Lange et al. 2004).

The stability analyses (Fig. 6) suggested 7 and 17 networks were appropriate starting points for parcellating the cortex. As the results will reveal, these parcellation solutions were excellent for capturing significant components of the regional variation that could be replicated across datasets and independently revealed by seed-based analyses. However, the focus on 7- and 17-network solutions should not be taken to imply that meaningful properties are absent in alternative parcellation schemes. By focusing on both a relatively coarse solution (7-network) and fine-resolution solution (17-network), we were able to survey the solution space broadly.

Parcellation maps of the cerebral cortex were generated for both 7-network and 17-network solutions for the Discovery sample and replicated in the Replication sample. The reliability analysis was conducted to illustrate the stability of the topographic boundaries that the solutions converged upon. In this regard, a powerful feature of analyzing large data samples is that the analyses are able to detect the presence of stable cerebral networks and also to establish the boundaries of regions with a high degree of confidence, including contiguous regions that may be part of distinct networks. As a final step the full sample (N = 1000) was used to compute parcellations that represent our best estimates of the networks (Figs. 11 and 13).

Confidence maps
A useful visualization of the cortical parcellation is to look at the confidence of each spatial location belonging to its assigned network. We used the silhouette measure (Rousseeuw 1987) from the clustering literature for this purpose (Figs. 8 and 10). The silhouette of a data point (spatial location in our case) measures the similarity (correlation in our case) of the data point to other data points of the same cluster (network in our case) compared with data points belonging to the next closest cluster. The resulting silhouette at each spatial location lies between -1 and 1, so that a larger value indicates higher confidence of the spatial location in belonging to its assigned network. A negative value indicates that the connectivity profile at the spatial location is on average closer to the next closest cluster than to its assigned cluster. A negative value is therefore unlikely, but is still possible because the clustering cost function is not equivalent to the silhouette measure.

Correlation maps and correlations between regions

Large-scale cortical networks can be reliably estimated. To better understand the meaning of the networks resolved by the clustering technique, all salient results were followed up with focused analyses using seed-based regional analysis. The coordinates for all seed regions used in these analyses can be found in Tables 1-5. For these analyses, group-averaged functional connectivity maps were used to inspect the validity of clustering results and to visualize differences in connectivity patterns of regions in sensory and association cortices.

Each region consisted of single surface vertex (~4 mm x 4 mm) but should be considered spatially more extensive because of the spatial smoothing and intersubject averaging. Correlation maps were obtained by computing the Pearson’s product moment correlation between the region’s preprocessed resting fMRI time course and the time courses of all other vertices across the cortical mantle. To obtain a group-averaged correlation z-map, the correlation map of each subject in the group was converted to individual subject z-map using Fisher’s r-to-z transformation and then averaged across all subjects in the group. The Fisher’s r-to-z transformation increases normality of the distribution of correlations in the sample. For subjects with multiple runs, the individual subject z-maps were first averaged across the runs before submitting to the group
average. An inverse Fisher’s r-to-z transformation was then applied to the group-averaged correlation z-map yielding a group-averaged correlation map.

To quantify functional connectivity among regions, Fisher’s r-to-z transformed correlations were computed among the regions for each subject within a group. For several targeted, a priori analyses, classical statistical tests, including t-tests (e.g., see Figs. 20 and 21) and ANOVA (e.g., see Figs. 22 and 27), were performed on the z-transformed correlations using Matlab 7.4 (Mathworks, Natick, USA) or SPSS 18.0 (IBM, Armonk, USA). All tests survive Bonferroni correction for multiple comparisons.

Selecting regions for functional connectivity analysis

Throughout the analyses, seed regions for functional connectivity were selected using different criteria depending on the purpose of the analysis. In all cases, if a particular dataset was used for selecting the region (e.g., Discovery sample), functional connectivity was always computed with a different dataset (e.g., Replication sample), thus providing an unbiased measurement of correlation strength. We detail the method used for region selection in the results as they are implemented for each particular analysis in the Results section. The following procedures describe the general strategies adopted.

First, when testing for seed-based confirmation of resolved networks, the estimated network boundaries and confidence maps of the Discovery sample were used to derive regional vertices to be tested in the Replication sample (e.g., see Fig. 16). Regions were chosen for (1) maximal spatial coverage of estimated networks, (2) avoiding network boundaries, and/or (3) their confidence in network assignments. We also defined new regions based on the correlation maps from the Discovery sample. For example, new regions might be chosen to be at or near the peaks of the correlation maps.

Second, for some analyses we utilized task-based fMRI to select regions. For example, visuotopic and functional characteristics revealed using fMRI can be used to estimate visual areas in the human (Hadjikhani et al. 1998; Sereno et al. 1995). The Caret software database provides estimated locations of multiple visual areas that were mapped into Caret PALS space using surface-based registration of an individual case in Hadjikhani et al (1998), although the foveal and peripheral extents of these areas are
likely to be underestimated (Van Essen 2004). Landmark-based surface registration between FreeSurfer and Caret PALS allowed us to utilize these fMRI-defined visuotopic regions for guiding our selection of regions in FreeSurfer surface space (e.g., V3A in Fig. 25). In addition, we also considered peak activation coordinates reported in fMRI literature (e.g., see Fig. 27). When the peak coordinates were reported in MNI space, we projected the coordinates to FreeSurfer surface space. The mapping between MNI152 volumetric space and FreeSurfer surface space is detailed in our companion study (Buckner et al. submitted). In cases where the peak activation coordinates were reported in the atlas space of Talairach and Tournoux (1988), the coordinates were first mapped to FSL MNI152 space (Lancaster et al. 2007) before being projected to FreeSurfer surface space.

Third, probabilistic histological maps in FreeSurfer surface space allowed for the selection of regions within histologically-defined areas (e.g., see Fig. 22). Postmortem human brains of fifteen subjects with no history of neurologic or psychiatric diseases were processed and analyzed (Amunts et al. 1999; Schleicher et al. 1999; Schormann and Zilles 1998). The histological sections were aligned to postmortem MR volume of the same brain using nonlinear warping (Schormann and Zilles 1998) to build an undistorted 3-dimensional histological volume. Cytoarchitectonic areas, including V1 (Amunts et al. 2000) and hOc5/MT+ (Malikovic et al. 2007) were segmented using observer-independent criteria (Schleicher et al. 1999). The MR volumes were segmented to separate white matter from other tissue classes, and the segmentation was used to generate topologically correct and geometrically accurate surface representations of the cerebral cortex using FreeSurfer (Fischl et al. 2008). The cortical surfaces of the fifteen subjects were registered to FreeSurfer surface space and the histological areas were sampled onto the surface space. While there were fifteen subjects, each cytoarchitectonic area was only analyzed in at most ten subjects.

Prior work has demonstrated good across-subject alignment of lower order cortical areas in the surface coordinate system, with average misregistration errors as small as 2-3 mm for V1 (Fischl et al. 2008; Hinds et al. 2008; Yeo et al. 2010a), which is around the spatial resolution of the present fMRI data. For higher-order regions such as BA44, BA45 and hOc5/MT+, intersubject agreement is worse, with average
misalignment errors in the order of 6-12 mm (Fischl et al. 2008; Yeo et al. 2010a; 2010b), but still an improvement from standard volumetric alignment (Amunts et al. 1999). In the case of histologically defined hOc5, considered to be putative MT+ (Malikovic et al. 2007), we were able to verify (not shown) that the probabilistic map of hOc5 in FreeSurfer surface space (Yeo et al. 2010b) was consistent with that of MT+ defined in Caret PALS space (Van Essen 2004) and peak MT+ coordinates reported in fMRI attention literature (Shulman et al. 1999). Certain anatomical landmarks were also useful in the selection of regional vertices. For example, the calcarine fissure was used as a guide to select regions in the lower and upper visual field representations as well as in the central and peripheral visual field representations within V1 (e.g., see Fig. 22).

Comparison of network boundaries with cytoarchitectonic areas

In addition to their utility for selecting regions, the probabilistic histological maps were useful in relating the estimated network boundaries to human cytoarchitectonic areas. Because the Statistical Parametric Mapping (SPM) Anatomy toolbox contained a more complete set of probabilistic histological maps of the same subjects in MNI Colin27 volumetric space (Eickhoff et al. 2005), we projected these probability maps to FreeSurfer surface space by establishing spatial correspondence between Colin27 and FreeSurfer surface space using the same procedure as that used for mapping between MNI152 volumetric space and FreeSurfer surface space (Buckner et al. submitted).

Cytoarchitectonic areas common to both datasets were those of the primary motor cortex (areas 4a and 4p; Geyer et al. 1996), premotor cortex (area 6; Geyer 2004), primary somatosensory cortex (areas 3, 2 and 1; Geyer et al. 1999), early visual cortex (areas 17 and 18; Amunts et al. 2000), hOc5/MT+ (Malikovic et al. 2007) and BA44/45 (Amunts et al. 1999). Consistent with previous discussion about surface-based versus volume-based registration, we found Eickhoff’s probabilistic maps in FreeSurfer space to be more diffuse than the maps obtained from the purely surface-based approach, implying poorer intersubject alignment. Consequently, for cytoarchitectonic areas common to both datasets, the surface-based probabilistic maps were used (Fischl et al. 2008; Yeo et al. 2010b) (e.g., see Fig. 22). We were also able to verify reasonable overlap (not shown) between the projected Eickhoff’s maps and the purely surface-based probabilistic maps.
for areas common to both datasets, substantiating the validity of the mapping between the
Colin27 space and FreeSurfer surface space.

Effect of resting condition on functional connectivity

For certain analyses, it was important to check that findings were not the result of
overt eye movements that might shift edges and visual boundaries in and out of the
central field. The core dataset (N = 1000) employed an eyes open rest condition because
it is comparable to visual fixation in terms of signal strength (Van Dijk et al. 2010) but
can be acquired in studies that do not employ a setup for visual display. To examine the
effects of the task employed during the resting-state, the effect of condition was analyzed
for certain key analyses (e.g., for analyses that quantified the functional connectivity
strengths among visual regions). As the results will show, the type of resting condition
(EOR, ECR or FIX) is not a significant factor influencing our results (e.g., see Fig. 17).

Visuotopic fMRI data

The analyses of the visual cortex involved the visuotopic organization of the V1-
V3 complex. The fMRI data were analyzed in the native subjects’ volumetric space and
the results sampled onto FreeSurfer surface space and averaged across subjects. The
details of the analysis, which provided eccentricity estimates of the visual representation
in the V1-V3 complex, are described elsewhere (Hinds et al. 2009). A 1mm smoothing
kernel was applied to the averaged eccentricity estimate in FreeSurfer surface space.
Because of the limited range of visual angle that could be stimulated in the MRI scanner,
and because fixational eye movements that occur during visual stimulation prevent stable
stimulation of the fovea, the eccentricity estimates did not cover the representation of the
periphery or of the center of visual field within the V1-V3 complex (Hinds et al. 2009;
Polimeni et al. 2005), but were sufficient for our analyses.

Distribution of parcellations and raw data

A primary result of this study is the parcellation of cortical networks and the
estimation of boundaries of regions within the networks. The parcellations of parietal and
prefrontal cortices, in particular, represent demarcations of complex topographical
regions that have been perplexing to understand in relation to task-based functional
neuroimaging studies. We have uploaded the parcellations in Caret PALS surface space
into the Surface Management System Database (SumsDB) for open use (Dickson et al.
2001) (link under construction). The parcellations in FreeSurfer surface space can be
downloaded from http://surfer.nmr.mgh.harvard.edu/fswiki. The raw fMRI data from the
1000 subjects will be made openly available to researchers using the procedures
established by the OASIS data releases (Marcus et al. 2007; 2010) and the 1000
Functional Connectomes Project (Biswal et al. 2010).

Results

Estimates of cerebral networks are reliable

The cerebral cortex was parcellated into multiple networks using clustering. The
parcellations resulted in networks that involved primarily adjacent areas (e.g., visual
cortex) and networks that involved areas widely distributed throughout the cortex (e.g.,
heteromodal association cortex). Figure 7 shows the 7-network estimates for the
Discovery and Replication samples. A total of 97.4% of the vertices were assigned to the
same networks across both datasets. Varying the particular choice of binarization
threshold (ranging from 5% to 15%) and smoothing (ranging from no smoothing to 6mm
FWHM) minimally affected the results (not shown). Figure 8 shows the confidence
(silhouette) value for each vertex with respect to its assigned network for the 7-network
estimate. Regions close to the boundaries between networks were less confident in their
assignment. Spatial variation within individual components of the estimated networks
was also observed beyond the boundary regions. Often these low-confidence regions
anticipated further fractionation of the networks into smaller subnetworks that emerged
when larger numbers of networks were allowed (e.g., compare the lateral prefrontal
extent of the orange network in Fig. 7 with its confidence map in Fig. 8, and then note
subsequent fractionation of this region in Fig. 9). Figure 9 shows the 17-network
estimates for the Discovery and Replication data samples, and Figure 10 shows the
confidence map for the Discovery dataset. For the 17-network estimate, 97.0% of the
vertices were assigned to the same networks across both datasets.
Estimates of cerebral networks from 1000 subjects

To provide the best estimates of the cerebral cortical networks, clustering was performed on the full sample of 1000 subjects. Figures 11 and 13 show the 7- and 17-network parcellation estimates. Several results are notable. A salient feature of the estimated networks is the separation of the early sensory and late motor cortices (blue and purple) from association cortex, consistent with the observation that early sensory and late motor regions exhibit dense local anatomical connectivity in primates (Felleman and Van Essen 1991; Jones et al. 1978; Markov et al. 2010) and preferential local functional coupling in humans (Sepulcre et al. 2010). Sensory and motor cortices, whose functional connectivity networks were preferentially local, comprised only 35% of the cerebral mantle and were the exception in terms of network structure.

The majority of the human cerebral cortex is comprised of multiple, distinct networks of association areas. The association networks in the 7-network estimate converged and extended upon networks previously described in the resting-state literature, including those referred to as the dorsal and ventral attention (green and violet respectively; Fox et al. 2006), the frontoparietal control (orange; Dosenbach et al. 2007; Vincent et al. 2008) and the default (red; Buckner et al. 2008; Greicius et al. 2003) networks (Fig. 12). We also note that the 7-network parcellation of the parietal cortex is similar to those proposed using seed-based approaches (Vincent et al. 2008) and using the areal boundary detection method (Cohen et al. 2008; Nelson et al. 2010). The convergence of multiple different analysis approaches suggests that the parcellation is intrinsic to the resting-state data rather than an artifact of the algorithm used.

Generally, the 17-network estimate fractionated the 7-network estimate into smaller subnetworks. Some aspects of the fractionation, such as the emergence of a parahippocampal-retrosplenial-lateral parietal network, are anticipated by other studies.
using hierarchical-clustering techniques (e.g., Andrews-Hanna et al. 2010). Other aspects of the fractionation were unexpected, such as the emergence of subnetworks within the visual and motor cortices that did not respect areal boundaries but rather appear to align with topographic organization. In the following sections, we quantify and further explore the patterns of functional connectivity that give rise to these networks.

Insert Figures 11, 12 and 13 About here

A cautionary note about potential artifacts

Before exploring the estimated networks in more detail, it is important to point out aspects of the data that are difficult to interpret because of potential fMRI signal blurring across gyri and signal loss associated with susceptibility (Ojemann et al. 1997). Figure 14A illustrates one example. Somatomotor, auditory and posterior insular cortices are correlated within a single network (also see Fig. 11). The ventral portion of somatomotor cortex is clustered with the auditory cortex in the 17-network parcellation (Fig. 13). While non-human primate tracing studies suggest auditory and somatomotor cortices are connected via multiple areas within the insular cortex (Disbrow et al. 2003; Friedman et al. 1986; Mesulam and Mufson 1982; Mufson and Mesulam 1982), an equally likely explanation for the observed correlation is blurring of the BOLD signal across the Sylvian fissure (Fig. 14A). We could not find a way, in these data, to resolve whether the coupling was an artifact of limited resolution or a true, coupled network.

Figure 14B illustrates a second example of how fMRI signal blurring might affect the interpretation of the results. In this case, the primary somatosensory cortex (S1) and primary motor cortex (M1) are clustered within the same network (Fig. 11). While there is anatomical evidence of direct connectivity between S1 and M1 in the macaque (Jones et al. 1978; Pons and Kaas 1986), we are unable to resolve whether the coupling was an artifact of limited resolution due to the close proximity of M1 and S1 in volumetric space.
As an example of uncertainty occurring near regions of MR susceptibility, Figure 14C illustrates a cream-colored network of regions in the temporal pole and orbital frontal cortex (also see Fig. 11). While there is anatomical evidence from the primate tracing literature supporting the existence of this network (Carmichael and Price 1995; Kondo et al. 2003; Moran et al. 1987), the spatial distortion and signal loss caused by MR susceptibility creates uncertainty in the location of the network boundaries.

Sensory and motor cortices exhibit topographically-specific functional connectivity

The sensory and motor cortices were clustered separately from the association cortex in the 7-network estimate (Fig. 11). This result by itself suggests that sensory and motor cortices distinguish themselves from distributed networks of association areas. Within the sensory and motor networks, there were a number of further observations. Of most interest, the 17-network parcellation fractionated the sensory and motor cortices into subnetworks (Fig. 13). Specifically, early visual regions formed two distinct subnetworks that did not respect areal boundaries. Somatomotor cortex was similarly fractionated along its lateral extent. Our hypothesis is that these fractionations reflect topographic organization – topographic representation of visual space in the visual regions and topographic representation of body space in the somatomotor regions.

Visual topography. The visual network in the 7-network estimate (Fig. 11) was fractionated into two separate subnetworks (purple and bright red) in the 17-network estimate (Fig. 13). The boundary between the two visual subnetworks cut perpendicularly across the calcarine fissure, suggesting the division of the early visual areas into central and peripheral components. To evaluate this possibility, Figure 15 overlays the eccentricity estimates of the Visuotopic dataset over the boundaries of the two separate visual subnetworks. The early visual areas were divided into two subnetworks along an isoeccentricity line of approximately 4°. We refer to these two subnetworks as “central”
and “peripheral”, although an immediate question arises as to whether the division of lower visual areas into central and peripheral components extends to higher visual areas. The particular traveling wave paradigm used in the Visuotopic dataset was designed to estimate visual eccentricity within the V1-V3 complex and is therefore unreliable outside the complex (Wandell et al. 2007). To gain further clarification on visual areas outside the V1-V3 complex, we inspected the boundaries of the 17-network parcellation overlaid on the map of approximate human visual areas provided by Van Essen (2004). The boundary between the central and peripheral representations continues through the extrastriate visual areas consistent with the possibility that the division of lower visual areas into central and peripheral components generally applies to the extrastriate cortex with certain caveats that will be taken up in the Discussion.

To assess the validity of the clustering analysis of visual cortex, six seed regions were selected from the Discovery sample (Table 1), and their fcMRI maps were computed using the Replication sample. The regions were selected to include V1 and V3 regions that fell within the central and peripheral representations. Using the calcarine fissure, histological V1 estimates (Amunts et al. 2000; Fischl et al. 2008) and the network boundaries as landmarks, two regions labeled V1c and V1p were selected to correspond to central and peripheral V1 respectively. Using the probabilistic histological maps of the SPM Anatomy toolbox (Eickhoff et al. 2005), two regions labeled V3cv and V3pv were selected at or near visual area V3v (Rottschy et al. 2007; Wilms et al. 2010) corresponding to the central and peripheral representations respectively. The two remaining regions were selected from the extrastriate regions of the central and peripheral visual subnetworks. In all cases, the confidence (silhouette) map of the 17-network estimate from the Discovery sample (Fig. 10) was used as a guide.
The fcMRI maps of the six seed regions confirm the network demarcations (Fig. 16). Compared with the other seed regions of the central visual system, V1c demonstrated weaker correlation to the extrastriate regions of the central visual system. This is reflected by the lower confidence of V1c in its network assignment as shown in Table 1. Consistent with this observation, as the number of networks in the clustering analysis was increased (not shown), the central V1 region separated from the extrastriate component of the central visual system.

To quantify the dissociation between the central and peripheral representations within the visual subnetworks, Figure 17A shows polar plots of the correlation of V1p and V1c with five regions in the Replication sample. Since the Discovery and Replication samples consist of resting data collected under the eyes open rest condition, the patterns of functional connectivity were also quantified for the Task Effect dataset (Fig. 17B). The results revealed that the central and peripheral V1 seed regions displayed distinct patterns of functional connectivity that generalized across multiple data acquisition conditions including eyes closed rest and visual fixation.

Although there are differences in visual field properties, such as magnification factors and receptive field sizes, between the central and peripheral regions of the V1-V3 complex, these differences vary smoothly from central to peripheral vision within an area (Balasubramanian et al. 2002; Dow et al. 1981; Van Essen et al. 1984). To explore this
further, functional connectivity was examined among seed regions spanning the eccentricity axes of V1 and V3v (Fig. 18). Results did not suggest a sharp transition in functional connectivity between V1 and V3v seed regions moving from central to peripheral representations. The resulting division of the V1-V3 complex along the isoeccentricity line of 4° was therefore likely driven by the functional connectivity of visual regions outside the V1-V3 complex or may be an artifact of the small number of networks being mandated by the analyses.

Somatomotor topography. The 7-network parcellation estimate clustered the somatomotor cortex into a single network (the blue network in Fig. 11). Figure 19 shows the boundaries of the 7-network estimate overlaid on the probabilistic histological maps of areas 6 (Geyer 2004), 2 (Grefkes et al. 2001) and 5L (Scheperjans et al. 2008a; 2008b). The histological estimates of areas 1, 3 and 4 (Geyer et al. 1996; Geyer et al. 1999) are sandwiched between areas 2 and 6 and are not shown. Recent work (Amunts et al. 2010) has delineated three additional premotor areas anterior to the ventral half of area 6 shown in Figure 19; the ventral half of area 6 in Figure 19 is therefore an underestimation. Based on these areal references, the somatomotor network likely includes MI (area 4) and caudal premotor area 6, SI (areas 3, 1 and 2) and most, if not all of early somatosensory area 5L. The somatomotor network also includes a small portion of the mid-cingulate sulcus and possibly area 5M (not shown; Scheperjans et al. 2008a; 2008b).
The 17-network parcellation divided the somatomotor strip into dorsal and ventral subnetworks across the axis that represents body space (Fig. 13). To investigate this division, the parcellations were compared to activation maps of 24 subjects who were instructed to move their tongue, hand or foot in response to a visual cue (for a detailed explanation of this dataset, see Buckner et al. submitted). As shown in Figure 20A, the boundary between the dorsal and ventral somatomotor subnetworks was roughly positioned between the hand and tongue representations. To quantify this observation, seed regions were selected from the left hemisphere hand, foot and tongue activation maps and verified to fall within the probabilistic histological map of area 4 (Fischl et al. 2008; Geyer et al. 1996). Figure 20B shows pairwise correlations computed among the hand, foot and tongue regions averaged over 1000 subjects (Hand coordinates: -41, -20, 62; Foot coordinates: -6, -26, 76; Tongue coordinates: -55, -4, 26). The hand-foot correlation was significantly higher than the hand-tongue correlation (p < .001) and foot-tongue correlation (p < .001). Thus, like the visual system, functional coupling forms networks within the somatomotor system that reflect topographic organization.

There were two further results that must be interpreted cautiously because of volumetric signal blurring. The 7- and 17-network parcellations of somatomotor cortex included both the precentral and postcentral representations of body space thus forming networks that spanned areas (M1 and S1). This observation is difficult to interpret because precentral and postcentral gyri abut each other in volumetric space (see Fig. 14B). Similarly, the ventral somatomotor network in the 17-network parcellation included parts of the insula and auditory cortex, perhaps reflecting a polysynaptic circuit of functional coupling linked to speech movements and hearing one’s own voice. We do not interpret this observation because of their volumetric proximity (see Fig. 14A).

Asymmetry of functional coupling varies across somatomotor topography
Analysis of asymmetries in functional coupling is beyond the scope of this paper. However, we observed an interesting variation in the asymmetry of functional coupling that reinforces the observation of functional differences along the somatomotor body representation. Specifically, pairwise correlations between homotopic pairs of hand, foot and tongue representations (Hand coordinates: ±41, -20, 62; Foot coordinates: ±6, -26, 76; Tongue coordinates: ±55, -4, 26) were measured between the hemispheres (Fig. 21A). The homotopic hand correlation was significantly weaker than that of the homotopic foot (p < .001) and tongue (p < .001) correlations. We are unable to rule out the possibility that the higher correlation between homotopic tongue regions is an artifact of subjects moving their tongues during scanning.

To explore the somatotopy of interhemispheric fcMRI beyond the hand, foot and tongue representations, we estimated the sequence of vertices lying in the shortest path connecting the left tongue region with the left hand region and those lying in the shortest path connecting the left hand region with the left foot region. For each left hemisphere motor vertex, we found the corresponding right hemisphere vertex that was maximally correlated with it in the Discovery sample. Figure 21B plots the correlation between the left hemisphere vertices, arranged ventral to dorsal, and the corresponding right hemisphere vertices in the Replication data sample. Defining the maximally correlated right hemisphere vertices in the Discovery sample avoided bias in the correlation values and the issue of picking truly homotopic representations in either hemisphere. Consistent with Figure 21A, the maximal tongue correlation was higher than that of the foot, which was in turn higher than that of the hand. The region in between the hand and foot representations, possibly corresponding to the trunk representation, also displayed higher maximal interhemispheric correlation than those of the hand or foot representations.
The observed somatotopy of interhemispheric fcMRI is consistent with non-human primate studies that have shown that the representations of midline structures in S1 and M1, such as the face and trunk, have denser callosal connections than those of distal limbs, such as the hand and foot (Gould et al. 1986; Jones and Wise 1977; Killackey et al. 1983).

Hierarchical processing within a canonical sensory-motor pathway

Parcellation of the cerebral cortex into distinct networks will not capture information about interactions between regions that fall across separate networks. This is particularly problematic because the canonical system-level description of cortical processing involves interactions across hierarchical pathways of sensory and motor areas. The above analyses leave open the question of how the distinct networks interact as is expected for sensory-motor pathways.

To explore this question, we selected the canonical sensory-motor pathway that extends from primary visual cortex to the precentral motor regions (including the putative homologue of FEF) via the motion-sensitive MT+ complex and posterior parietal cortex at or near putative human LIP. In the macaque literature, this pathway has been extensively studied in relation to sensory-guided decisions resulting in eye movements and associated processes linked to spatial attention (e.g., Andersen and Buneo 2002; Colby and Goldberg 1999; Gold and Shadlen 2007; Shadlen and Newsome 2001). In the human literature, this pathway has been studied both in relation to spatially-directed movements and also in relation to spatial attention, with components of the pathway sometimes referred to as the dorsal attention system or network (Corbetta and Shulman 2002). Most critically, the anatomic relations between the areas within the pathway have been extensively explored beginning with the seminal work of Maunsell and Van Essen (1983).

Early visual cortex. Analysis focused initially on the bottom of the sensory-motor pathway by investigating functional connectivity between V1 and putative human MT+2.

In humans, the MT+ complex is used to denote the putative human homologue of macaque area MT and neighboring visual areas that are sensitive to motion stimuli (DeYoe et al. 1996). Here we are able to constrain the location of MT+ using surface...
For this analysis, two V1 regions were selected in dorsal (V1_{cd}) and ventral (V1_{cv}) central V1 corresponding to the lower and upper visual field representations. Two additional V1 regions were selected in dorsal (V1_{pd}) and ventral (V1_{pv}) peripheral V1 corresponding to the lower and upper visual field representations. Two MT+ seed regions (MT+_d, MT+_v) were selected following the dorsoventral extent of the surface-based probabilistic histological map of MT+ (Malikovic et al. 2007; Yeo et al. 2010b). The MT+_d and MT+_v seed regions likely correspond to peripheral and central visual field representations respectively (Huk et al. 2002; Maunsell and Van Essen 1987) and were analyzed to illustrate differential connectivity within MT+. Because of the over-representation of the lower visual field within macaque MT (Maunsell and Van Essen 1987), the distinct MT+ seed regions might also represent the lower visual field, although human fMRI studies have so far failed to yield evidence of this representation bias within MT+ (Amano et al. 2009; Kolster et al. 2010; Tootell et al. 1995). In the following analyses, MT+ was either analyzed as two regions using the extreme seed regions (MT+_d and MT+_v) or as a single region using the center seed region (MT+) for analyses that did not require the complexities of topographic distinctions. A single aMT+ (anterior MT+) region was chosen anterior to and outside the histological MT+ region. The regions are shown in Figures 22A and 24; their coordinates are reported in Table 2.

---

Multiple seed regions are used throughout the paper. The abbreviation of the names of these seed regions obeyed the following convention: the suffix following a region indicates relative spatial location within the region, while the prefix preceding a region indicates relative spatial location outside the region. Therefore, MT+_d is a seed region within the dorsal aspect of the MT+ complex, while aMT+ is a seed region anterior to and outside the MT+ complex.
Figure 22B quantifies the differential functional coupling of the four V1 regions with MT+ and aMT+ within the Replication sample. V1 showed strong functional coupling to MT+ and significantly weaker coupling to aMT+ (p < .001 for both MT+_v and MT+_d). The dorsal and ventral MT+ regions also demonstrated differential functional coupling with the four V1 regions, confirmed by a 2x2x2 ANOVA including eccentricity (central or peripheral), polar angle (upper or lower visual field), and MT+ region (dorsal or ventral). Both MT+ regions were more strongly coupled with the lower visual field V1 seed regions than the upper visual field V1 seed regions (p < .001). Furthermore, dorsal MT+ was more strongly coupled with peripheral V1 than central V1 (p < .001), while ventral MT+ was more strongly coupled with central V1 than peripheral V1 (p < .05). These results suggest the topographic pathways between V1 and the MT+ complex are largely consistent with the visual field representations of the two areas.

Since V1 is a relatively large structure compared with MT+, to ensure the results were robust to the particular choice of the V1 seed regions, Figure 23 shows fcMRI maps of the aMT+, MT+_d and MT+_v regions computed using the Replication dataset. By all accounts, V1 is functionally coupled to MT+ while aMT+ shows minimal coupling, leading to their separation into distinct networks in the cortical parcellation.

Visual association and parietal association cortices. Moving up the sensory-motor pathway, the functional connectivity of MT+ and aMT+ with parietal and frontal cortices was next examined. Figure 24 shows the fcMRI maps of MT+ and aMT+ seed regions computed using the Replication sample with views focusing on the parietal and lateral frontal cortices. In the parietal lobe, both MT+ and aMT+ demonstrated correlation with the SPL and IPS, but little or no correlation with the inferior parietal lobe (IPL). In the frontal cortex, correlations were mostly limited to the precentral sulcus and gyrus. Compared with the MT+ seed region, the aMT+ seed region demonstrated
stronger correlation with the parietal and frontal cortices. The MT+ and aMT+ seed
regions were also maximally correlated with different parts of the parietal and frontal
cortices, suggesting differential influence on nearby regions of sensory-association
cortex.

To quantify the pattern of differential functional coupling, we computed the
correlation of the MT+ and aMT+ seed regions with four visual, four parietal and two
frontal cortical regions (Fig. 25A). Two of the visual cortex regions, V1_{cd} and V1_{pd}, were
previously used in the V1-MT+ connectivity analysis. V3A and V4 were selected based
on their high correlation with MT+ in the Discovery sample and named using the
approximate map of human visual areas (Van Essen 2004) as reference. The four parietal
regions were chosen at or near the IPS. Three of the parietal regions (IPS2, SPL7A,
SPL7P) were selected based on a meta-analysis of fMRI literature of tasks that reportedly
activate the human homologues of macaque areas AIP (anterior intraparietal), LIP (lateral
intraparietal) and PIP (posterior intraparietal) respectively. The final parietal region,
IPS3_m, was selected using the Discovery sample to be physically between IPS2 and
SPL7A. The parietal regions were labeled based on their proximity to the probabilistic
histological maps. In particular, IPS2 is at or near area hIP2 at the anterior most part of
IPS (Choi et al. 2006), while SPL7A and SPL7P are at or near areas 7A and 7P of the
SPL (Scheperjans et al. 2008a; 2008b). Finally, IPS3_m is on the medial wall of IPS at or
near area hIP3 (Scheperjans et al. 2008a; 2008b). The dorsal frontal region, putatively
FEF, was selected based on the meta-analysis of fMRI literature of saccade tasks. The
ventral frontal region PrC_v (precentral ventral) was selected based on its high correlation
with aMT+ in the Discovery sample. The locations of the visual, parietal and frontal
regions are reported in Table 2. Table 3 summarizes the set of fMRI studies used to
derive the coordinates of IPS2, SPL7A, SPL7P and FEF.
Figure 25B shows the polar plots of the regional correlations using the Replication sample. To ensure that the results were not the result of overt eye movements, the polar plots were also replicated using the Task Effect dataset in Figures 25C and 25D. In all cases, MT+ had significantly stronger correlation with early visual cortex as compared with aMT+. In contrast, aMT+ had significantly stronger correlation with the parietal and frontal regions compared with MT+. MT+ and aMT+ are strongly coupled to one another ($r = 0.30$ in the Replication sample). Thus, consideration of functional coupling between these regions in detail suggests that early visual areas are coupled to regions at or near MT+, which are in turn directly (or indirectly through intermediate regions, such as aMT+) coupled to parietal and frontal regions associated with sensory-motor integration. The differential coupling of MT+ and aMT+ resulted in their inclusion into distinct cortical networks.

**Frontoparietal interactions.** We next considered the differential functional coupling of FEF and PrCv with the parietal cortex. Figure 26 shows the fcMRI maps of FEF and PrCv computed using the Replication sample. While both FEF and PrCv demonstrated strong correlation with the SPL and IPS, differences in correlation patterns also emerged. Specifically, PrCv was strongly correlated with more ventral portions of rostral SPL and IPS, while FEF was strongly correlated with caudal SPL and IPS. To quantify this phenomenon, we computed the correlation of FEF and PrCv with five parietal regions at or near SPL and IPS. Four of the parietal regions (IPS2, IPS3m, SPL7A, SPL7P) were the same as those used in the previous analysis. Using the Discovery sample, a fifth parietal region was selected on the lateral wall of rostral IPS, within what is often termed the frontoparietal control network (orange; Fig. 11). Since the region was located at or near the histological map of hIP1 (Choi et al. 2006) projected to
FreeSurfer space, we labeled the seed IPS1. The regions are displayed in Figure 27A and their coordinates reported in Table 2.

------------------------------------------------------------------

Insert Figures 26 and 27 About here

------------------------------------------------------------------

Figure 27B shows the correlation of FEF and PrCv with the five parietal regions computed in the Replication sample, arranged in rostral (lateral) to caudal (medial) order. The rostrolateral IPS regions (IPS1, IPS2, IPS3m) were more strongly correlated with PrCv than FEF, while the mediocaudal SPL regions (SPL7A, SPL7P) were more strongly correlated with FEF than PrCv. A 2x6 ANOVA including frontal regions (FEF, PrCv) and parietal regions (IPS1, IPS2, IPS3m, SPL7A, SPL7P) found a significant interaction (p < .001). In particular, FEF was more strongly correlated with the three IPS seeds (all p < .001) while PrCv was more strongly correlated with SPL7A and SPL7P (both p < .001). These results reveal differential coupling between distinct parietal and frontal regions, likely reflecting multiple pathways involved in sensory-motor integration (Kurata 1991; Rizzolatti et al. 1998; Tanné-Gariépy et al. 2002).

Hierarchical analysis. Assuming a visual hierarchy similar to that proposed by Maunsell and Van Essen (1983) exists in human cerebral cortex, V1 is expected to be near the bottom of the hierarchy and FEF to be near the top (also see Felleman and Van Essen 1991; Ungerleider and Desimone 1986). While there are uncertainties as to the exact homologies of our MT+ and aMT+ seed regions, they are likely to be in the middle of the hierarchy with aMT+ higher than MT+. In our analysis, we found that V1 and MT+, which are close together in the hierarchy, have stronger correlation than V1 and aMT+, which are farther apart in the hierarchy (Figs. 22 and 25). We also found that aMT+ and FEF, which are closer in the hierarchy, have stronger correlation than MT+ and FEF, which are farther apart in the hierarchy (Figs. 24 and 25).

These results suggest that correlation between regions in the visual hierarchy may provide some insight into the organization of the pathways. To explore this hypothesis,
we examined the arrangement of six seed regions (V1pd, V3A, MT+, aMT+, SPL7A, FEF) discussed earlier based on the assumption that stronger correlations are consistent with closer positioning in the processing hierarchy. By examining alternative arrangements of regions, the analysis was able to investigate which particular arrangement was most consistent with the functional connectivity pattern. Figure 28 illustrates this approach. Figure 29 shows the two best hierarchical arrangements of the six regions when seeking a five-level hierarchy using the Replication sample. In both cases, the relative ordering of the regions within the functional hierarchy agrees well with the proposed macaque visual hierarchy of Maunsell and Van Essen (1983). By contrast, alternative arrangements of the visual areas lead to large proportions of violated constraints (Figs. 29D and 29E).

Control analyses using the Discovery set shows that the fcMRI strengths of all pairs of the six seed regions are inversely correlated (r = -0.78, p < .001) with respect to the hierarchical distance between the regions in the hierarchy as defined by Felleman and Van Essen (1991). By contrast, the fcMRI strengths of all pairs of the six seed regions are not correlated (p = 0.23) with respect to the physical distance between the seed regions. These results suggest that spatial proximity does not explain these correlations; rather, the pattern of correlations reflects relative positions of regions within the hierarchy.

These findings converge on two main results. First, there are functional interactions between networks but the interactions are selective. V1 shows minimal coupling with association regions within parietal cortex but it does couple with MT+. The between-network interactions also do not typically violate the network organizations revealed earlier by the clustering approaches: regions show stronger functional coupling to other regions within their network as contrast to regions outside their network. Second, when examined together, the pattern of correlations between regions in different networks is consistent with a hierarchical organization by which sensory information could influence regions associated with motor control (Fig. 29).

These findings converge on two main results. First, there are functional interactions between networks but the interactions are selective. Parietal and prefrontal association cortices possess multiple regions with distinct connectivity profiles

The analyses above describe separate sensory and motor networks, and address the question of how sensory and motor networks might interact through intermediate areas such as aMT+. However, these networks make up only a minority of the human cerebral cortex. Networks of widely distributed regions comprise the majority of the human cerebral cortex as illustrated by the violet, orange, and red networks in the 7-network solution (Fig. 11). The network complexity expands when the 17-network parcellation is considered (Fig. 13). These association networks will be the remaining focus of the results. First, we examined the topography of parietal and frontal association cortices to quantitatively illustrate that multiple neighboring regions possess markedly different functional connectivity fingerprints. Next we explored the relations between distributed regions to demonstrate that the association cortex is comprised of multiple, interdigitated association networks.

**Parietal association cortex.** The basic approach employed to characterize the connectivity properties of parietal cortex was to extend the strategy applied in Figure 25 to construct polar plots that quantify coupling with multiple, distributed cortical regions. Following the work of Passingham et al. (2002), we refer to these plots as “functional connectivity fingerprints” with the idea that the graphical representation will facilitate the visualization of similarities in connectivity properties between regions as well as any differences that make them unique. The plots are quantitative in that eccentricity displays the strength of functional coupling between each seed region and a single target region.

For this analysis, multiple regions within parietal cortex were selected to cover the IPL and immediately adjacent portions of the SPL. Regions were further selected to survey distinct networks as revealed by the clustering maps. Some of the regions were used previously in the sensory-motor pathway analysis (IPS2, SPL7A). Other regions (PF, PGa, IPS3l, PGpd and PGpv) were selected using the Discovery dataset and then labeled according to the probabilistic histological maps. In particular, the PF and PGa seed regions were at or near human inferior parietal areas PF and PGa, respectively.
(Caspers et al. 2006; 2008), while the IPS3 seed region was on the lateral lip of the IPS at or near human hIPS3 (Scheperjans et al. 2008a; 2008b). PGp\textsubscript{d} and PGp\textsubscript{v} corresponded to the dorsal and ventral aspects of area PGp in the IPL (Caspers et al. 2006; 2008). One additional seed region at or near the temporoparietal junction (TPJ) was selected based on the peak coordinates reported in a human fMRI study of mental state inference (Saxe and Powell 2006), which accords well with the predicted mean peak in a recent meta-analysis on the same topic (Van Overwalle and Baetens 2009).

Twenty-two cortical target regions were distributed over the lateral and medial aspects of the cerebral cortex such that multiple regions covered each association network. Four of the cortical regions (aMT\textsuperscript{+}, MT\textsuperscript{+}, FEF and PrC\textsubscript{v}) were used previously in the sensory-motor pathway analysis. Many labels for the frontal seed regions reflect gross anatomical landmarks as atlas-based human histological references were not available; subscripts denote relative positions. It is worth noting that target region 6vr\textsuperscript{+} was selected to be anterior to the map of premotor area 6 (Geyer 2003) and labeled to reflect a new delineation of the ventral precentral sulcus (Amunts et al. 2010). Target region PFC\textsubscript{v} fell within the histological map of BA45 (Amunts et al. 1999). The coordinates of the parietal seed regions and cortical target regions are reported in Table 4.

The results are illustrated in Figure 30. Parietal association cortex is comprised of multiple regions that can show similarities but often display markedly different functional connectivity fingerprints. Visual inspection of the plots allows appreciation of the resemblance of correlation patterns for parietal seed regions that cause them to fall within common networks. For example, the PGp\textsubscript{d}, PGp\textsubscript{v}, and TPJ seed regions all fall within the default network as defined in the extant neuroimaging literature. Their connectivity fingerprints are largely defined by their correlations with other association and limbic regions, and near complete absence of correlations with visual regions including MT+.
and aMT+. This general fingerprint pattern can be directly contrasted with parietal regions such as those represented by IPS2 and SPL7A that are associated with distributed cortical regions linked to sensory and motor function (e.g., strong correlations with MT+ and aMT+). These distinct parietal regions (IPS2 and SPL7A) are likely at or near the putative human homologue to macaque AIP and LIP and fall within the functional network that has been discussed as the dorsal attention network in the human literature and described in detail above in Figures 22 to 29.

There are also subtle differences across regions that fall within the same broad networks. For example, while parietal seed regions TPJ, PGp, and PGp₄ are strongly correlated with posterior cingulate cortex (PCC) and the precuneus (pCun), PGp has comparatively stronger correlation to retrosplenial cortex (RSP) and parahippocampal complex (PHC). In contrast, TPJ has the strongest correlation with posterior superior temporal sulcus (STSₚ) and lower correlation with RSP and PHC. PGp₄ has the strongest correlation with medial prefrontal cortex (PFCₘ). These differential correlations account for the fractionation of the posterior IPL into three components in the 17-network estimate (Fig. 13) and may be important to the functional properties of the region.

**Frontal association cortex.** Analysis of frontal association cortex applied the same approach as for parietal association cortex. The 8 frontal seed regions selected for analysis were among the cortical targets in the parietal plots discussed previously. The 22 cortical target regions selected for analysis were distributed throughout the cortex and selected so that multiple target regions covered each association network. Eleven regions were carried forward from the previous analysis of the parietal cortex (e.g., IPS2, SPL7A, FEF, PrCₜ, aMT+ and MT+) and these were arranged in the same spatial locations in the polar plots (Cinga clockwise to pCun). The remaining 11 cortical target regions were unique to analysis of frontal cortex but are arranged in the plots so that cortical target regions at the same location in the polar plots belong to the same network in the 7-network estimate. The arrangement of the cortical target regions therefore facilitates the comparison of polar plots across the parietal and frontal figures. The coordinates of the frontal seed regions and cortical target regions are reported in Table 4.
Figure 31 shows the polar plots of correlations for the 8 frontal seed regions with the 22 target regions in parietal, temporal, frontal and cingulate cortices. Many of the same properties observed for parietal association cortex were again apparent. Figure 31 demonstrates that frontal seed regions in the same network generally share similar functional connectivity fingerprints that are distinct from those of neighboring seed regions belonging to a different network. A simple posterior-to-anterior hierarchy is not present as might be expected from some models of frontal hierarchy based on anatomical connectivity (e.g., Petrides 2005). Rather, regions with similar functional connectivity fingerprints appeared at posterior and anterior locations as evidenced by PFC_{ds}, which is considerably rostral to most of its partner regions, and PFC_{dp} which is considerably caudal to its partner regions.

The arrangement of the cortical target regions also allows a key feature of connectivity to be appreciated when frontal Figure 31 is directly compared to parietal Figure 30: parietal and frontal seed regions from the same network, for instance PG_{pd} and PFC_{ms}, have similar functional connectivity fingerprints. These similarities suggest that association cortex is made of parallel interdigitated networks of regions consistent with suggestions based on double-labeling analyses of monkey association cortex (Goldman-Rakic 1988; Selemon and Goldman-Rakic 1988). In our final analysis, we explored this possibility directly by comparing functional connectivity maps for multiple seed regions distributed across each association network.

*Association cortex is comprised of multiple, interdigitated large-scale networks*

The parcellations derived from clustering suggest that there are multiple, large-scale networks interdigitated throughout association cortex. Thus, components of the green, violet, orange and red networks in the 7-network estimates are spatially adjacent in the parietal, temporal and frontal cortices (Fig. 11). A similar organization is observed in the 17-network estimate (Fig. 13). However, such an impression could be an artifact of
the winner-take-all implementation of clustering that assigned each cortical vertex to a single network. The complex functional connectivity fingerprints demonstrated that regions within the same networks showed similar functional connectivity fingerprints even when distributed across the cortex, consistent with their inclusion in common networks, but also revealed differences between regions that suggest subtler organizational properties. In our final analysis, we sought to explore patterns of functional connectivity using an exclusively seed-based approach in a comprehensive manner to contrast connectivity patterns for multiple regions embedded within the same networks.

For this analysis, six left hemisphere seed regions from each of the four major association networks were analyzed beginning with the canonical sensory-motor network (known as the dorsal attention network in human neuroimaging literature). The ventral attention, frontoparietal control and default networks were subsequently explored. These four networks were identified in the 7-network estimate based on the Discovery dataset. Where possible we used the same seed regions as used by the other analyses in this paper. For this reason, the selected regions were not always the most confident in terms of network assignment as assessed by their silhouette plots or other means. Table 5 reports the coordinates of the seed regions.

The left hemisphere fcMRI maps of the seed regions were computed using the Replication dataset and illustrated in Figures 32 to 35. Each seed region is functionally coupled primarily to regions within the same network, thus largely confirming the 7-network estimate and the existence of multiple, large-scale distributed networks in human association cortex. The network patterns were even reproduced when target regions were isolated in relation to adjacent cortical regions (e.g., Fig. 33A). Thus, this verifies that the networks identified via clustering capture the predominant functional coupling patterns within association cortex. Note that this result is not obligated – the maps derived from the analysis of seed regions are not constrained to respect the borders of the networks defined by clustering. Furthermore, while the broad patterns confirmed the boundaries of the networks as expected, several exceptions were also observed.
Insert Table 5 and Figures 32, 33, 34 and 35 About here

Close inspection of the maps (Figs. 32 to 35) reveals evidence for crosstalk among the networks, consistent with the earlier analyses of the canonical sensory-motor pathway. For example, Figure 32C/D suggests interaction between the dorsal attention network and regions within the visual system, possibly related to the previously described hierarchical flow of information within the sensory-motor pathway (Fig. 29). In contrast, Figure 32F suggests functional coupling between the dorsal attention and the frontal components of the frontoparietal control and ventral attention systems.

A further observation is that the fcMRI maps of seed regions chosen from the same network anticipate fractionation of the networks in ways also suggested by the analysis of connectivity fingerprints. For example, the PHC seed region is strongly coupled with the RSP, but not with the full extent of the posterior cingulate (Fig. 35E). It is also strongly coupled to the IPL but not the anterior IPL. This suggests that the 7-network estimate is likely insufficient to capture the full complexity of the functional couplings across different brain regions. As predicted by the fcMRI map of the PHC seed, the 17-network estimate differentiates the posterior IPL, RSP and the posterior PHC into an IPL-RSP-PHC system (dark blue in Fig. 13) distinct from the other regions of the default network.

These collective results thus illustrate patterns of connectivity that are largely captured by a relatively small number of interdigitated, large-scale networks but also reveal more detailed properties that suggest crosstalk and fractionation within the major networks.

Discussion

The present results suggest association cortex comprises the majority of the human cerebral mantle and is made up of multiple, interdigitated association networks. The properties of association networks were found to be quite different from that of sensory
and motor cortices. Sensory and motor areas are embedded within cerebral networks that are organized in a topographic fashion forming preferentially local networks – meaning that adjacent areas tend to show strong functional coupling with one another. Hierarchical relations progress from early visual areas to premotor areas. By contrast, multiple association networks involve areas distributed throughout the cortex, always including discrete regions within prefrontal, parietal, temporal and midline cortices. These distributed association networks are interdigitated in a manner that yields complex zones, particularly in parietal and prefrontal association cortices. Within these zones, nearby regions possess markedly different connectivity patterns that can be explained by their being embedded within distinct association networks. In the following sections we explore the details of these patterns and discuss what the connectivity patterns suggest about how the human cerebral cortex may have expanded during evolution.

*The cerebral cortex comprises multiple, distinct functionally coupled networks*

A primary result of our analyses is the cerebral maps depicted in Figures 11 and 13. Figure 11 displays a coarse parcellation of the cerebral cortex into 7 functionally coupled networks, and Figure 13 displays a finer parcellation into 17 networks. These maps represent our current best estimate of the organization of the human cerebral cortex based on fcMRI. The large number of contributing subjects (N = 1000) and surface-based alignment procedures helped to detect topographical details with considerable confidence. However, these maps are still limited in resolution owing to between-subject averaging and the acquisition resolution of the data, and will presumably be improved in the future. At their present resolution, they have been surprisingly informative for providing insights into cerebral organization and, as will be illustrated by our companion paper, they also provide a basis to explore the organization of subcortical structures (Buckner et al. submitted).

Two broad properties are immediately apparent when examining the maps, which will be the focus of discussion. First, sensorimotor and visual cortices form their own networks in the coarse parcellation that are fractionated into subnetworks in the finer parcellation. The fractionations do not follow simple divisions such as between somatosensory and motor areas along the central sulcus, or between early (e.g., V1) and...
late (e.g., V3) retinotopic visual areas in the occipital cortex. We will discuss hypotheses about what these fractionations might represent in upcoming sections. Second, association cortex comprises multiple, interdigitated networks that are distributed throughout cortex. Multiple aspects of these networks, in particular the properties of the coarse networks displayed in Figure 11, have previously been described using seed-based (e.g., Biswal et al. 1995; Greicius et al. 2003; Fox et al. 2006; Vincent et al. 2006) and independent component analysis (e.g., Beckmann et al. 2005; Damoiseaux et al. 2006; De Luca et al. 2006) approaches. Many aspects of the organization, especially within the higher resolution parcellation (Fig. 13), are novel. We will discuss the details of the organization of association cortex in upcoming sections with particular focus on zones of parietal and prefrontal cortices that represent nexuses of convergence among multiple, distinct networks.

*Visual cortex displays local, topographically organized functional coupling*

Early visual areas were strongly functionally coupled to one another and only minimally correlated to regions outside of visual cortex. Examining the coupling properties more closely revealed evidence for an intrinsic gradient within the early visual cortex that likely corresponds to the transition from the central to peripheral visual field representations (Figs. 15 to 17). The division is not absolute (Fig. 18) but appears as an abrupt division into central and peripheral networks when assignments into distinct networks are forced, providing a convenient way to map the topographical organization across visual areas. Inspection of the boundaries of the functionally coupled networks on visual areas suggests that the division of lower visual areas into central and peripheral components might extend to higher visual areas. The ventral boundary of the central and peripheral visual systems continued outside the V1-V3 complex and divided V4v in two. Since the eccentricity representation of the V1-V3 complex is continuous through V4v (Brewer et al. 2005; Hadjikhani et al. 1998), it is likely that V4v was also divided into central and peripheral components. Anterior to V4v, at least two hemifield maps have been found, all of which have a distinctly large foveal representation and respond strongly to central visual stimuli throughout their extent (Brewer et al. 2005; Wandell et
al. 2005), and are therefore consistent with the inclusion of V8 (Hadjikhani et al. 1998) within the central visual system.

However, there were inconsistencies as might be expected because of limited resolution and the inherent complexity of the visual cortex (see Wandell et al. 2007 for a review). Multiple hemifield maps have been found in the extrastriate cortex lateral to the V1-V3 complex (DeYoe et al. 1996; Larsson and Heeger 2006; Tootell and Hadjikhani 2001), such as regions that are part of the object-selective lateral occipital complex (LOC; Malach et al. 1995) and motion-selective area MT+ (Huk et al. 2002; Malikovic et al. 2007; Tootell and Taylor 1995). The inclusion of these entire visual regions within the “central” visual system suggests a violation of the central-peripheral division in these areas, although we note that the ventral visual stream (of which LOC is a part) is dominated by signals from the fovea (Baizer et al. 1991). The dorsal boundary of the central and peripheral visual networks continued outside the V1-V3 complex and cut through the hemifield maps dorsal and lateral to V3v, possibly including V3A, V3B and V7 (Larsson and Heeger 2006; Swisher et al. 2007; Tootell et al. 1998). Because these regions have separate foveal representation from the V1-V3 complex (see Fig. 1 in Larsson and Heeger 2006) and because of the complex trajectory of the boundary through these regions, we were unable to judge whether the central-peripheral division applied to these regions.

The central-peripheral functional coupling of the human visual system is consistent with many aspects of known anatomy. Anatomical studies in non-human primates have shown that the topography of connections between visual areas generally respects the visual field representation (Cragg 1969; Maunsell and Van Essen 1983; Van Essen and Zeki 1978; Zeki 1969). For example, a region of V1 that responds strongly to a particular eccentricity and polar angle will project to the region of V2 that responds strongly to the same eccentricity and polar angle, presumably because of feedforward input (Van Essen and Zeki 1978). Because of the larger receptive field size of neurons in V2, the degenerated target area tends to be larger than that of the source lesion. Our result of higher functional connectivity strength between V1c and V3c (as well as between V1p and V3p) than between V1c and V1p may reflect the topography of anatomical connections within the visual system.
If anatomical connectivity respects visuotopic representation and functional connectivity is constrained by anatomical connectivity, a question then arises as to why the clustering analysis divided the visual areas (especially the lower visual areas) into central and peripheral regions rather than into upper and lower visual fields? A split along the eccentricity axis is supported by proposals that higher visual areas are organized according to central versus peripheral field bias (Baizer et al. 1991; Grill-Spector and Malach 2004; Levy et al. 2001), although such an organization has also been disputed (Larsson and Heeger 2006; Wandell et al. 2005). A more mundane and likely reason is that eccentricity representation runs in parallel across multiple visual areas in contrast with angular representation that alternates in visual field sign across multiple visual areas (see Fig. 1 in Larsson and Heeger 2006; Sereno et al. 1995). Because this study utilized smoothing and intersubject averaging to boost SNR, any topography in functional connectivity that respects the high spatial frequency of angular representation is likely to be washed out. The resulting limitation in spatial resolution might also explain why visual regions dominated by foveal signals are grouped entirely within the central visual system even though they possess quarterfield or hemifield representations spanning both central and peripheral vision.

Together these observations suggest that functional connectivity of the visual cortex followed the topographic organization of these areas up to a point. Certain observations, such as the lack of functional connectivity topography reflecting angular visual representation, could not be reconciled with prior anatomical observations. These differences may reflect the limitations of our approach, true differences between fcMRI and anatomical connectivity or novel connectivity findings that have yet to be revealed in anatomical studies. We will discuss these limitations and ambiguities later.

Somatomotor cortex displays topographical organization

Estimates of functional connectivity networks grouped multiple somatosensory and motor areas into a single functionally coupled network for the low-resolution estimate of cortical organization (Fig. 11) and into a dorsal-ventral division for the high-
Like visual cortex, the somatomotor network was characterized by its strong functional coupling to nearby areas but absence of functional coupling to distributed regions across the cortex (barring regions across the insular cortex). Even when regional analyses were explored that did not constrain the topography to form separate networks, no evidence was found for functional coupling to distributed cortical regions. Figure 19 shows that the motor component of the somatomotor network included MI (area 4) and caudal premotor area 6, while the somatosensory component included SI and most, if not all of early somatosensory area 5L. The somatomotor network also included a small portion of the mid-cingulate sulcus and possibly part of area 5M. Within the somatomotor cortex of non-human primates, areas 1 to 6 are densely, but not fully, connected (see meta-analysis in Felleman and Van Essen 1991) by association fibers that enter the white matter and re-enter the cortex (Jones et al. 1978). For example, these association fibers connect area 2 with areas 1, 3, 4, 5 and 6 (Jones et al. 1978; Pons and Kaas 1986), as well as area 4 with areas 2 and 6 (Matelli et al. 1986; Matelli et al. 1998; Muakkassa and Strick 1979), but not areas 1 and 3 (Jones et al. 1978; Pons and Kaas 1986). Jones et al. (1978) also reported “non-specific” local connections between adjacent primary somatosensory and motor areas (e.g., areas 3 and 4).

The non-human primate premotor area 6 has been subdivided into rostral and caudal areas that may provide further insight into the functional connectivity patterns (Barbas and Pandya 1987; Matelli et al. 1985; 1991; Zilles et al. 1995). The caudal premotor areas are densely and topographically connected to M1, but not to the prefrontal cortex. In contrast, the rostral premotor areas are connected to prefrontal cortex but not M1 (Barbas and Pandya 1987; Luppino et al. 1993; Matelli et al. 1986). The caudal premotor areas are also more densely connected to each other than the adjacent rostral premotor areas. While there are competing hypotheses over the exact homology between primate and human premotor areas (Geyer 2004; Petrides 2005; Rizzolatti et al. 1998), converging studies have suggested a rostrocaudal subdivision of human premotor cortex (see chapter 4.4 of Geyer 2004 for a review), which might reflect the absorption of caudal

---

4 Auditory cortex was also functionally coupled to the ventral somatomotor network. However, as illustrated in Figure 14, this may be an artifact of signal bleeding across the insula in volumetric space. For this reason, while the finding may reflect a meaningful functional interaction, we do not discuss it further in the present paper.
human area 6 into the somatomotor network as revealed by functional coupling. Despite evidence that the early somatosensory and late motor fields are densely integrated, we must be cautious of the possibility of fMRI signal blurring across the central sulcus, which may cause an overestimation of functional coupling between the parallel strips of SI, MI and premotor area 6.

Of most interest, the analysis also revealed a dorsoventral division of the somatomotor strip, which was confirmed by targeted regional analyses (Fig. 20). In non-human primates, the connections between the different somatosensory-motor areas are generally topographic, so that for example, the hand region of area 3 projects to the hand region of areas 1 and 2 (Jones et al. 1978; Pons and Kaas 1986). In addition, the somatomotor association fibers have been reported to terminate in mediolaterally oriented strips (see for example Fig. 4 in Jones et al. 1978; Jones and Wise 1977), although others have raised questions concerning the strip-like nature of callosal connections (Gould et al. 1986; Killackey et al. 1983). Our observations of fcMRI correlations within the human somatomotor cortex, whose anteroposterior extents were shorter than their mediolateral extents, were therefore consistent with the observations of ipsilateral strip-like anatomical connections. One possibility is that the dorsoventral boundary revealed by our clustering analysis might correspond to the boundary of the face and body representations.

**Evidence for a prototype distributed cortical pathway**

The results discussed above reveal interesting organizational properties of local networks of areas within sensorimotor and visual cortices. In considering the organization of the cerebral cortex, an immediate question arises as to how information in the sensory systems might propagate to influence motor representations? Functional connectivity is limited in its ability to provide insight into this question, but some aspects of the results are informative and consistent with anatomical and physiological studies of sensory-motor pathways.

The canonical sensory-motor pathway that has been studied in the monkey is the pathway that includes retinotopic visual cortex, the MT+ complex, parietal area LIP, and the FEF (e.g., Andersen et al. 1990; Colby and Goldberg 1999; Gold and Shadlen 2007; Shadlen and Newsome 2001). The basic idea is that incoming visual information
propagates from early visual areas to MT+, which provides constraints on decision processes that arise from interactions with LIP and FEF. FEF, in turn, interacts with motor regions to generate motor signals. Hierarchical anatomic connections support such a pathway (Felleman and Van Essen 2001; Maunsell and Van Essen 1983). The question here is whether the human functional connectivity results also reveal evidence for such a pathway and, if so, what properties emerge?

Of particular interest are the quantitative results presented in Figures 22 to 27 that reveal interactions between distinct networks. While primary visual cortex is largely absent functional coupling to association or premotor cortices, it is topographically coupled to MT+ (Fig. 22), which is in turn strongly coupled to aMT+ as well as modestly coupled to parietal regions including SPL7A (Figs. 24 and 25). aMT+ is functionally coupled to PrC, and FEF (Fig. 25) completing the pathway. While the organization of the human MT+ complex is still unresolved, human MT+ is thought to include the human homologues of macaque MT, MST and FST (Amano et al. 2009; Huk et al. 2002; Kolster et al. 2010). Based on the relative location of aMT+ with respect to MT+, aMT+ might correspond to macaque MST/FST (Maunsell and Van Essen 1983) or TEO/PIT (Felleman and Van Essen 1991; von Bonin and Bailey 1947). Our observation that aMT+ is less correlated with V1 than MT+ (Figs. 22 and 23) is therefore consistent with multiple studies showing that macaque TEO/PIT or MST/FST is less densely connected with V1 compared with MT (Distler et al. 1993; Felleman and Van Essen 1991; Markov et al. 2010). Although there are uncertainties to using functional connectivity to infer hierarchical arrangements among areas, if one uses the simple assumption that the more strongly two areas are functionally coupled together, the closer they are to one another in a processing hierarchy, a sensory-motor processing hierarchy emerges that is consistent with the extant literature (Figs. 28 and 29).

Analysis of interactions among networks illustrates a number of further points. Most critically, the hierarchy across networks reveals how a distributed network might serve as a bridge between sensory and motor networks that themselves possess preferentially local interactions (resulting in their parcellation into their own networks in Figs. 11 and 13). One speculation is that the distributed cortical network illustrated as the green network in Figure 11 -- and known within the neuroimaging literature as the dorsal...
attention system -- is the prototype distributed cortical network. It possesses multiple properties that are common to all association networks. Specifically, its component regions are distributed throughout temporal, parietal, and frontal cortices and show strong functional couplings between all pairs of regions (Fig. 32). We speculate that this network is a prototype because it is more strongly functionally coupled to extrastriate sensory regions and premotor regions than the remaining association networks that will be discussed later and also because it is well represented in the macaque. The presence of similar networks in humans and macaques suggests that they are homologous, and thus were present in the last common ancestor, which lived about 25-30 million years ago (Pilbeam and Young 2004). As will be discussed in the next section, the remaining distributed association networks, which in the human represent the majority of association cortex, display the same general organization but appear to have lost direct functional coupling to sensory and motor regions, at least insofar as measured by intrinsic functional connectivity.

Another important feature of this hierarchy is apparent when one considers finer details of the functional coupling patterns. Within the broad hierarchy, there is evidence for specialization indicative of parallel hierarchical arrangements. This is perhaps best illustrated by the differential functional coupling of premotor regions FEF and PrCv with the multiple regions localized around the superior parietal lobule (Figs. 26 and 27). Anatomical tracing work in the macaque has suggested two segregated sensory-motor pathways from parietal cortex to dorsal and ventral aspects of frontal cortex, including premotor cortex (Kurata 1991; Rizzolatti et al. 1998; Tanné-Gariépy et al. 2002) and the frontal eye fields (Petrides and Pandya 2006; Stanton et al. 1995). These frontoparietal connections have a dorsomedial to ventrolateral axis: dorsal portions of caudal frontal cortex are preferentially connected to medial and dorsal parts of parietal cortex including the superior parietal lobule and medial parietal cortex, while caudal ventral frontal cortex preferentially communicates with lateral and ventral aspects of parietal cortex and largely lacks connections with dorsal and medial parietal areas. Our demonstration that PrCv was strongly correlated with more ventral portions of rostral SPL and IPS, while FEF was strongly correlated with caudal SPL and IPS (Figs. 26 and 27) is consistent with descriptions of frontoparietal sensory-motor circuits in the macaque. Thus, evidence for
specialization of subpathways is present in this canonical sensory-motor pathway. Taking
the speculation that this canonical pathway represents the prototype distributed
association network, it is tempting to wonder whether the interdigitated association
networks that comprise the remaining human association cortex are evolutionary
expansions of this basic prototype with multiple, interdigitated pathways that have
become nearly completely differentiated.

Association cortices are nexuses of regions with distinct connectivity fingerprints.
Association cortex, in particular parietal cortex near the inferior parietal lobule,
has been challenging to characterize. Human association cortex shows disproportionate
expansion in relation both to macaque and great apes (Preuss 2004; Van Essen and
Dierker 2007; Hill et al. 2010). In a few instances, it is an open question as to whether
homologies should be expected (Orban et al. 2006). For example, in his seminal work in
1909, Korbinian Brodmann noted that the human inferior parietal lobule included two
cytoarchitectonic areas that are absent in the monkey (areas 39 and 40). The possibility
that these association areas are vastly expanded in hominid evolution, or are even novel
areas altogether, figured prominently in the classic description of disconnection
syndromes by Geschwind (1965). For these reasons anatomic connectivity in the monkey
cannot uniformly be presumed to apply to the human. Adding further complication,
neighboring regions of association cortex are often active across quite distinct forms of tasks
suggested to have functional diversity (e.g., Culham and Kanwisher 2001). As extreme examples
of functional diversity, parietal regions near the superior parietal lobule, including those
discussed in the preceding section, respond during sensory-motor decision tasks
(Corbetta and Shulman 2002). Regions near the temporoparietal junction respond during
social tasks that require participants to infer what others are thinking (Saxe 2006; Van
Overwalle and Baetens 2009), and regions within the caudal portion of the inferior
parietal lobule respond during episodic remembering (Cabeza et al. 2008; Vilberg and
Rugg 2008; Wagner et al. 2005).

Our results demonstrate that parietal association cortex includes multiple nearby
regions that possess markedly different connectivity profiles that parallel similar
distinctions in prefrontal cortex. The results in parietal cortex are anticipated by both
anatomic studies in the monkey and prior studies using human functional connectivity. Specifically, the caudal portion of macaque 7a, labeled Opt by Pandya and colleagues (Pandya and Seltzer 1982), has connections to the parahippocampal cortex, retrosplenial cortex, and posterior cingulate (Seltzer and Pandya 1994; Andersen et al. 1990; Suzuki et al. 1994; Lavenex et al. 2002). Nearby areas, such as LIP, are preferentially connected to visual association cortex and premotor areas leading Andersen et al. (1990) to note that “area 7a appears to be very different from other visual areas in the inferior parietal lobule in that it is the only area that connects to some of the highest centers of the brain.” Examination of functional connectivity of parietal association cortex in the human has also revealed notable diversity. Vincent et al. (2006) illustrated that neighboring parietal regions are functionally coupled to distinct sensory-motor and limbic circuits. In later studies, parietal association cortex was found to possess between three (Vincent et al. 2008) and four (Nelson et al. 2010) distinct zones distinguished by their functional connectivity profiles (see also Sestieri et al. 2011).

Differential functional coupling across parietal and prefrontal regions are displayed in Figures 30 and 31. Drawing from Passingham and colleagues (2002), we refer to these regional connectivity profiles as ‘fingerprints’ because they illustrate the connectivity patterns across regions that make them distinct. In examining the many fingerprints, several principles emerge that provide insight into cortical organization. First, nearby regions can show abrupt transitions in their connectivity fingerprints. The transitions from SPL7A to IPS3l and from IPS3l to PGpd are such examples. SPL7A, which may be at or near the human homologue to macaque LIP, is functionally coupled to extrastriate (MT+ and aMT+) and premotor (FEF and PrCv) regions. IPS3l shows a fundamentally distinct connectivity fingerprint with coupling to prefrontal regions that are within dorsolateral prefrontal cortex (PFC\(_l\) and PFC\(_lp\)) and amodal posterior temporal association regions (ITG). IPS3l is absent coupling to sensory or motor regions. PGpd is distinguished by prominent functional coupling to limbic regions including posterior cingulate (PCC), retrosplenial cortex (RSP), and the medial temporal lobe (PHC). This tripartite division separates the major parietal zones that form the dorsal attention, frontoparietal control, and default networks discussed extensively in the human neuroimaging literature (green, orange, and red networks in Fig. 11).
Second, within these broad divisions there are further distinctions that demarcate more subtle regional differences. Across these regions, most connectivity properties are shared but there are also key differences, forming ‘connectional families’ of regions (see Passingham et al. 2002 for discussion). These differences within connectional families lead to the finer parcellation observed in Figure 13 and are likely of functional importance. For example, the TPJ and PGpv possess similar connectivity fingerprints, and both fall within the broader network that is globally called the default network. However, the TPJ is preferentially coupled to medial prefrontal regions (PFC$_{dm}$), the posterior cingulate cortex (PCC) and precuneus (pCun), and the superior temporal sulcus (STS and STS$_p$). While PGpv possesses a broadly similar fingerprint, it is also prominently coupled to regions associated with the medial temporal lobe memory system (RSP and PHC). This is of particular interest because both of these parietal association regions have been proposed to be involved with higher mental functions linked to internal mentation and social cognition (see Buckner et al. 2008 for review), but functional distinctions have also been noted (e.g., Rosenbaum et al. 2007).

The final organization principle that emerges is that association regions belonging to the same connectional families can always be found widely distributed across the cortical mantle. Contrasting the fingerprints of regions within prefrontal cortex (Fig. 31) with those falling within parietal cortex (Fig. 30) illustrates this last principle. PFC$_{dm}$ and TPJ are prime examples. These regions possess nearly the same functional connectivity fingerprints that differ from nearby regions within their own lobes. This accounts for why these distributed regions form such tightly coupled functional connectivity networks and suggests that association cortex might be best conceptualized as a series of interdigitated, distributed networks.

**Association cortex is comprised of multiple, interdigitated large-scale circuits**

The majority of the human cerebral cortex is made up of multiple large-scale networks that include functionally coupled regions distributed across the brain. Such organization is apparent in prior studies (e.g., Beckmann et al. 2005; Damoiseaux et al. 2006; De Luca et al. 2006; Fox et al. 2006; Greicius et al. 2003; 2004; Vincent et al. 2008) and is evident in all of the analyses presented here. By analyzing the complete
topography of the cortical surface, we were further able to illustrate that the multiple, distributed networks are interdigitated with one another forming complex convergence zones in parietal and prefrontal association cortices (Figs. 32 to 35). What do these patterns suggest about the organization of the cerebral cortex?

At the broadest level, these observations emphasize the need to adopt network approaches when exploring cerebral function. By network approach, we refer to the idea that the relevant functional unit may be the interconnected network itself, as suggested by Mesulam (1981; 1986) and Goldman-Rakic (1988). Mesulam (1981) proposed a network approach as an alternative to centrist approaches to localization, in which complex functions relied on specific cortical areas exclusively devoted to that function. While recognizing that functional specializations exist among areas of the same network, the network framework emphasizes that functions arise as emergent properties of these reciprocally connected systems of brain areas (see Fig. 4 of Mesulam 1981; 1990). In other words, distributed systems of areas, spanning different cortical lobes and subcortical structures, form functional units via their dense interconnections, giving rise to complex behavior. This is a quite different organization than is evident in sensory cortex, which is characterized by dense connectivity among local areas. The two frameworks are not entirely different because all areas are presumably embedded within systems of interacting brain areas; however, the focus in many theories is on processing specialization within areas and processing hierarchies among neighboring areas. The present analyses suggest that functional unit of interest may be the distributed network itself.

Goldman-Rakic (1988) offered three specific anatomic observations that provide evidence for distributed cerebral networks. First, prefrontal and parietal areas that are directly connected to one another also tend to have convergent projections to additional temporal and limbic areas (see Fig. 3 of Goldman-Rakic 1988). Second, interconnected association areas are tied together by common thalamic connections. And third, arguing against a typical hierarchical model of cortical organization, interconnected association areas tend not to have laminar projection patterns with clear feedforward and feedback relations (also see Felleman and Van Essen 1991). We suspect that the distributed networks that comprise the majority of human association cortex are networks of this
type – highly interconnected, without strong hierarchical relations among areas, and
tegrated into a common functional unit of some form. This does not mean that areas
within prefrontal and parietal cortices are making the same contributions to the network,
but the emphasis does shift to asking how the separate networks make distinct functional
contributions rather than asking how different areas within prefrontal or parietal cortices
may be locally differentiated. That is, association cortex is characterized by multiple
modules (Bullmore and Sporns 2009) that are each comprised of nodes distributed widely
across the cortex.

Of further interest, the distributed cerebral networks converge on regions of
association cortex that are late to develop in terms of myelination (see Fig. 3 of Catani
and ffytche 2005) and cortical surface area (Hill et al. 2010), and are expanded in the
human brain relative to the modern macaque brain (Van Essen and Dieker 2007). For
these reasons, it is likely that distributed association networks have been under strong
selective pressure to expand in recent hominid evolution. The network parcellations
presented in Figures 11 and 13 provide a current best estimate of the organization of the
interdigitated networks that comprise human association cortex.

Caveats and limitations
Measuring functional connectivity is not the same as directly measuring
anatomical connectivity. Functional connectivity is constrained by anatomic connectivity
(e.g., Johnston et al. 2008; Honey et al. 2009) but those constraints are not restricted to
monosynaptic connectivity. For example, functional coupling is present between the two
hemispheres for striate cortex in the macaque (Vincent et al. 2007) while
interhemispheric connections are absent except at the border of V1 (Van Essen et al.
1982). The pervasiveness of functional coupling is both a weakness and strength of the
technique as it allows one to map large-scale polysynaptic circuits, but leaves ambiguities
and uncertainties, which will require follow-up by other methods such as diffusion
imaging techniques and detailed examination of homologies to non-human primates.
Cerebrocerebellar circuits are a place that perhaps best illustrates that functional
connectivity is constrained by anatomy but is more pervasive than monosynaptic
connectivity. Cerebrocerebellar circuits – which are exclusively polysynaptic (Evarts and
Thach 1968; Kemp and Powell 1971; Strick 1985) – demonstrate functional coupling that tracks the contralateral organization of anatomic projections and is topographically specific as described in our companion paper (Buckner et al. submitted). Thus, functional connectivity is informative but should not be considered a direct measure of anatomic connectivity. Functional connectivity also appears sensitive to other factors, including recent experience and the state of the subject during scanning (Fox and Raichle 2007; Moeller et al. 2009; Buckner 2010). An assumption made in the present paper is that the dominant contribution to the measured correlations reflect stable properties of cortical architecture – an assumption we believe is warranted but nonetheless needs to be made explicit as boundary conditions and violations of this assumption may emerge.

A further limitation of the present work is resolution. Even at the relatively finer resolution of the 17-network estimate, discrete components of a given network likely span multiple cytoarchitecturally distinct cortical areas. The association networks described in this paper are at a coarser resolution than the networks inferred by Goldman-Rakic (1988) and others in the macaque. Our limited data resolution, as a result of voxel size, smoothing and intersubject averaging including potential errors in surface-based alignment, may miss important features of the cortical topography and the results should be interpreted accordingly. Future, high resolution studies of individuals may provide better estimates of cortical topography.

A final limitation is our use of clustering to parcellate the cerebral cortex. The assumption made by the clustering approach is that each vertex belongs to a single network. Our seed-based analyses (Figs. 32-35) suggest that this is a reasonable beginning point for analysis even though crosstalk exists between networks. However, there are specific places where the parcellation results might be particularly sensitive to inaccuracies, including the characterization of cortical regions that serve as putative hubs of communication between networks (Buckner et al. 2009; Hagmann et al. 2008; Mesulam 1998). We also note that the 17-network estimate does not cleanly fractionate individual networks within the 7-network estimate, implying that cortical networks are not spatially organized in a strictly hierarchical fashion\(^5\), like that suggested in the toy

\(^5\) Here “hierarchy” refers to the spatial organization of the networks rather than the concept of “hierarchical processing pathways”.

61
example (Fig. 5). Our efforts to enforce strict subdivisions of coarser networks by using hierarchical clustering (not shown) failed to provide stable results across the Discovery and Replication datasets. Recent advances in graph theoretic clustering approaches are promising in providing the possibility for regions to belong to multiple networks or communities (e.g., Ahn et al. 2010).

Conclusions

Different regions of the cerebral cortex display distinct characteristics. Functional connectivity of retinotopic visual areas display dense local functional coupling that is organized across areas in a fashion that respects functional topography. Association cortex is comprised of multiple, interdigitated large-scale networks that, while exhibiting crosstalk, possess predominantly parallel organization. The map of these cerebral networks is provided as a reference for future functional characterization and confirmation by complementary approaches that can directly visualize anatomic connectivity.

Notes: Four V1 seed regions were selected using the calcarine fissure, histological V1 estimates (Amunts et al. 2000; Fischl et al. 2008) and the 17-network boundary estimate in the Discovery dataset. V1<sub>pd</sub> and V1<sub>pv</sub> were from the dorsal and ventral parts of peripheral V1, likely representing the ventral and dorsal peripheral visual fields respectively. V1<sub>cd</sub> and V1<sub>c</sub> were from the dorsal and ventral parts of central V1, likely representing the ventral and dorsal central visual fields respectively. MT+<sub>d</sub>, MT+ and MT+<sub>v</sub> seed regions were selected from the dorsal, center and ventral parts of the histological map of the MT+ complex, so that MT+<sub>d</sub> and MT+<sub>v</sub> likely represented peripheral and central visual fields respectively. Based on the over-representation of the lower visual field within macaque MT (Maunsell and Van Essen 1987), it is possible that the three MT+ seed regions might also represent the lower visual field. aMT+ was selected to be anterior and outside the MT+ histological map. V3A and V4 were selected based on their high correlation with MT+ in the Discovery sample and named using the approximate map of human visual areas (Van Essen 2004) as reference. FEF and PrC<sub>v</sub> were selected from the caudal frontal
cortex, while IPS2, IPS3m, SPL7A, SPL7P and IPS1 were at or near IPS. FEF, IPS2, SPL7A and SPL7P were derived from the meta-analysis of fMRI studies (see Table 4).

The PrCv region was selected based on its correlation with aMT+. IPS3m was chosen spatially between IPS2 and SPL7A. IPS1 was chosen on the lateral wall of rostral IPS. IPS2, IPS3m, SPL7A, SPL7P and IPS1 were named using the probabilistic histological maps of the parietal cortex as reference (Choi et al. 2006; Scheperjans et al. 2008a; 2008b). Coordinates reflect the approximate center location based on the MNI atlas space.

Notes: For papers that only report right hemisphere coordinates, left hemisphere coordinates were obtained by reflection across the midline. Coordinates reflect the approximate center location based on the MNI atlas. For IPS2, tasks generally involved perception of 3D objects. Studies reporting responses at or near SPL7A used saccadic eye movement tasks. Studies reporting responses at or near SPL7P involved tasks requiring surface/orientation discrimination. FEF coordinates come from studies of saccadic eye movements.

Notes: Where possible, seed regions were carried forward from previous analyses (i.e., IPS2, SPL7A, FEF, PrCv, aMT+ and MT+; see Tables 2 & 3). Seed regions PF and PGa were at or near human inferior parietal area PF and PGa, respectively (Caspers et al. 2006; 2008). The IPS3l seed region was selected to be on the lateral lip of the IPS at or near human hIPS3, while the 5Ci seed region corresponded to the human posterior cingulate sulcal region 5Ci (Scheperjans et al. 2008a; 2008b). PGpd and PGpv corresponded to the dorsal and ventral aspects of area PGp in the inferior parietal lobule (Caspers et al. 2006; 2008). The TPJ seed region was selected based on the peak coordinates reported in a human fMRI study of mental state inference (Saxe and Powell 2006) which accords well with the predicted mean peak in a recent meta-analysis on the same topic (Van Overwalle and Baetens 2009). Seed region 6vr+ was selected to be anterior to the map of premotor area 6 (Geyer 2003) and labeled to reflect a new cytoarchitectonic delineation within the ventral precentral region (Amunts et al. 2010). Seed region PFCv fell within the histological map of BA45 (Amunts et al. 1999; Fischl et al. 2008). The remaining seed regions were selected to provide comprehensive coverage of the lateral and medial aspects of the cortical surface and such that each association network was represented by multiple targets. Labels for the remaining seed regions were determined according to gross anatomical landmarks and given subscripts to denote relative positions: Cing = cingulate sulcus; pCun = precuneus; ITG = inferior temporal gyrus; PCC = posterior cingulate cortex; PFC = prefrontal cortex; PHC = parahippocampal cortex; RSP = retrosplenial cortex; STS = superior temporal sulcus. Subscripts a = anterior; p = posterior, l = lateral, m = medial, d = dorsal and v = ventral. Coordinates reflect the approximate center location based on the MNI atlas.

Notes: The confidence of the seed regions in their network assignment is computed from the Replication dataset. Coordinates reflect the approximate center location based on the MNI atlas.
Figure Legends

Figure 1 Surface coordinate system for fMRI analysis. For each subject, the T2* images yielding BOLD-contrast fMRI data (A) were registered to the T1-weighted structural data (B). The cortical gray-white and pial surfaces were estimated from the structural data. The red lines show the estimated gray-white surface (A, B). Pial surface is shown in C. The gray-white surface was inflated into a sphere (D). The inflated spheres were then aligned across subjects using surface-based registration of the cortical folding pattern, resulting in a common spherical coordinate system (E). BOLD data of individual subjects (A) can then be projected onto the spherical coordinate system (E) in a single transformation step to reduce artifacts due to multiple interpolations.

Figure 2 Examples of intrasubject surface extraction and registration of structural-functional images. Examples of extracted cortical gray-white surfaces (red lines) are overlaid on T2* and T1 images of three random subjects in their native T1 space. Imperfections are apparent in BOLD data especially in regions of susceptibility artifact (e.g., orbital frontal cortex).

Figure 3 Signal-to-noise ratio (SNR) maps of the functional data from the full sample (N = 1000). The mean estimate of the BOLD fMRI data SNR is illustrated for multiple views of the left hemisphere in Caret PALS space. A = anterior, P = posterior, D = dorsal and V = ventral.

Figure 4 Cortical regions utilized in constructing functional connectivity profiles. A total of 1175 regions are sampled uniformly on the surface-based representations of the left and right hemispheres within the FreeSurfer surface coordinate system and shown here in Caret PALS space, where each red patch represents the location of a single regional vertex. Each vertex in the surface coordinate system is characterized by its profile of functional connectivity to the 1175 regions. The visually non-uniform distribution of the regions in Caret PALS space is due to the non-linear deformation from FreeSurfer space
to Caret PALS space. This image thus also serves to illustrate the subtle differences between the two surface space coordinate systems.

**Figure 5** Toy example illustrating clustering. (A) Hypothetical points are scattered in a structured fashion on a two-dimensional canvas. Clustering aims to recover the underlying structure. (B) Example solutions for $M = 2, 3, 4$ or $5$ clusters are shown. The solutions for $M = 2$ or $5$ clusters agree with visual assessment of the underlying structure and are therefore useful representations. On the other hand, seeking $3$ or $4$ clusters does not lead to satisfying solutions because solutions are ambiguous. For example, the $M = 3$ solution is not unique in the sense that an “equally good” alternate solution is for one group of points in the red cluster to be grouped with the orange cluster. Seeking $M = 3$ or $4$ clusters is therefore unstable in the sense that different random initializations of the clustering algorithm lead to different “equally good” solutions. In the present study we employed a stability analysis to estimate the numbers of clusters and also examined both a relatively coarse solution (7-network) and fine-resolution solution (17-network) so as to survey the solution space broadly (see Fig. 6).

**Figure 6** 7 and 17 networks can be stably estimated. Instability of the clustering algorithm is plotted as a function of the number of estimated networks for the vertex-resampling variant of the stability analysis applied to 1000 subjects. The clustering algorithm is less stable with increasing number of estimated networks, which is an expected property since the number of estimated networks enlarges the solution space (and thus complexity) of the clustering problem. The local minima of the graphs (marked with asterisks) indicate the number of networks that can be stably estimated by the clustering algorithm. The stability analysis suggests that 7, 10, 12 or 17 networks can be stably estimated. Resampling the ROIs yields almost identical results and is not shown. Here we focus on the 7- and 17-network estimates to provide a broad survey of the solution space.
Figure 7 Discovery and Replication of a 7-network cortical parcellation. The 7-network estimates are highly consistent across the Discovery (n = 500) and Replication (n = 500) datasets. 97.4% of the vertices were assigned to the same network.

Figure 8 Confidence of 7-network estimate in Discovery dataset. Confidence (silhouette) value for each vertex with respect to its assigned network is shown for the Discovery dataset. Regions close to the boundaries between networks were less confident of their assignment, although we also observed structured spatial variation within individual components of the estimated networks, such as lateral prefrontal cortex, which foreshadows its division in the 17-network estimate (Fig. 10).

Figure 9 Discovery and Replication of a 17-network cortical parcellation. The 17-network estimates are highly consistent across the Discovery (n = 500) and Replication (n = 500) datasets. A total of 97.0% of the vertices were assigned to the same network.

Figure 10 Confidence of 17-network estimate in Discovery dataset. Confidence (silhouette) value for each vertex with respect to its assigned network is shown for the Discovery dataset. Again, regions close to the boundaries between networks were less confident of their assignment, while structured spatial variation were observed within individual components of the estimated networks.

Figure 11 A coarse (7-network) parcellation of the human cerebral cortex based on 1000 subjects. To provide the best estimates of the 7 cortical networks, clustering was performed on the fMRI data of the full 1000 subjects. A salient feature is the separation of the early sensory and late motor cortices (blue and purple) from the association cortex. The association networks converged and extended upon networks previously described in the resting-state literature, including the dorsal attention, ventral attention, frontoparietal control and the default networks.

Figure 12 Table of colors assigned to networks in the 7-network estimate. Common names associated with each network in the neuroimaging literature are included in the
This should not be taken to mean that our estimated networks correspond exactly to those in the literature or that the networks code solely for functions associated with their assigned name. For example, components of the green network are implicated in spatial attentional tasks (Corbetta and Shulman 2002) and so we refer to the green network as the dorsal attention system. However, from the macaque literature, components of the green network have also been described in relation to the hierarchical processing of sensory information (e.g., Felleman and Van Essen 1991) and recruited in tasks involving sensory-guided decisions (e.g., Andersen and Buneo 2002).

**Figure 13** A fine-resolution (17-network) parcellation of the human cerebral cortex based on 1000 subjects. To provide the best estimates of the 17 cortical networks, clustering was performed on the fMRI data of the full 1000 subjects. The 17-network estimate fractionated the 7-network into smaller networks. Some aspects of the fractionations have been previously noted in other studies.

**Figure 14** Uncertain observations due to limited data resolution and MR susceptibility. When interpreting the clustering results, potential artifacts and uncertainties must be considered. Because of the close proximity of the somatomotor and auditory cortices (A) and the close proximity of the pre- and post-central gyri (B), we are unable to resolve whether the clustering of the somatomotor and auditory cortices (A) and the clustering of the primary somatosensory and primary motor cortices (B) are due to the result of fMRI blurring across sulci or a true, coupled network of distributed areas as predicted by macaque tracing studies. (C) The orbital frontal-temporopolar network (cream color) consists of temporopolar and orbital frontal regions that are affected by MR susceptibility. Since MR susceptibility spatially distorts the MR signal and reduces SNR, there is uncertainty in the exact boundary of the orbital frontal-temporopolar network and the true extent of the network is probably underestimated.

**Figure 15** Eccentricity estimates quantify the division of the early visual cortex into central and peripheral systems. Eccentricity estimates in the early visual areas of 4 subjects were averaged and overlaid on the boundaries (in black) of the 17-network
estimate. The boundary between areas 18 and 19 estimated from the Histological dataset is overlaid in green. The 17-network estimate divides the early visual areas along an isoeccentricity line of approximately 4°. Note that the eccentricity estimates are not reliable outside the V1-V3 complex.

**Figure 16** Evidence that the fractionation of the visual system reflects fcMRI topography within the visual cortex. Six left hemisphere seed regions were picked from the Discovery dataset: V1c and V1p correspond to central and peripheral visual field representation within V1 respectively; V3cv and V3pv correspond to central and peripheral V3v respectively; ExC and ExP correspond to two seed regions within the extrastriate visual cortex in the estimated locations of the central and peripheral visual fields (purple and bright red in center panel). The six seed regions are illustrated in the center panel and their coordinate locations are reported in Table 1. Their left hemisphere fcMRI maps were computed using the Replication dataset and arranged around the center panel. Note that the central visual seed regions are selectively correlated with the central visual representation, while the peripheral visual seed regions are selectively correlated with the peripheral visual representation.

**Figure 17** Quantification of fcMRI topography within the visual cortex and independence of the topography from task condition. (A) Quantification measures of functional connectivity strength are plotted in polar form for V1c (central V1) and V1p (peripheral V1) seed regions for the Replication dataset. Note that V1 refers to V1c for the V1p polar plot (blue) and V1p for the V1c polar plot (red). Coordinate locations for all six seed regions (V1c, V1p, V3cv, V3pv, ExC, ExP) are reported in Table 1. (B) Polar plots of (A) replicated with the Task Effects dataset (EOR = eyes open rest; ECR = eyes closed rest; FIX = fixation) to ensure that the results obtained using the EOR Replication dataset were not due to overt eye movements that might shift edges and visual boundaries in and out of the central field. Left figure shows V1p polar plot. Right figure shows V1c polar plot. The polar plots quantify the differential functional coupling of central and peripheral V1 with higher visual areas. The polar scales range from $r = -0.1$ (center) to $r = 0.7$ (outer boundary) in 0.2-step increments.
Figure 18 V1 and V3 functional correlations display a smooth transition from the central to peripheral representations. Correlation of two series of seed regions spanning the eccentricity axes of V1 and V3v is shown for the full 1000 subjects. V1 seed regions of low eccentricity are strongly correlated with V3 seed regions of low eccentricity. V1 seed regions of high eccentricity are strongly correlated with V3 seed regions of high eccentricity. There is a gradual transition in functional connectivity strength between the central to peripheral representations.

Figure 19 7-network boundaries on probabilistic maps of areas 6, 2 and 5L. Boundaries of 7-network estimate based on the full 1000 subjects are overlaid on the surface-based probabilistic histological maps of areas 6, 2 and 5L. The somatomotor network includes most, if not all of areas 2 and 5L, but only caudal half of area 6.

Figure 20 Evidence that the fractionation of the somatomotor cortex reflects fcMRI topography within the somatosensory and motor cortex. (A) Average fMRI activation maps of 24 subjects instructed to move their tongue (blue), right hand (red) or right foot (green) across separate conditions. Black lines correspond to boundaries of the 17-network estimate. The dorsoventral split of the somatomotor network occurs spatially between the tongue and hand activations. (B) Quantification of correlation strength between the left hemisphere tongue, hand and foot seed regions selected from the activation maps. Hand coordinates = -41, -20, 62; Foot coordinates = -6, -26, 76; Tongue coordinates: -55, -4, 26. Hand-foot correlation is significantly higher than hand-tongue correlation, which is in turn significantly higher than foot-tongue correlation.

Figure 21 Evidence that the interhemispheric fcMRI of homotopic regions within the primary motor cortex is topographically organized. (A) Correlation strength of left hemisphere tongue, hand and foot seed regions with corresponding contralateral seed regions averaged over all 1000 subjects. Right hemisphere vertices were obtained by reflection across the midline. Hand coordinates = ±41, -20, 62; Foot coordinates = ±6, -26, 76; Tongue coordinates = ±55, -4, 26. The tongue representation has the strongest
interhemispheric correlation, followed by the foot and then the hand. (B) Plot of interhemispheric correlation along the ventral (tongue) to dorsal (foot) extent of motor cortex. Maximal interhemispheric correlation is highest near the tongue representation and also peaks between the hand and foot representations, possibly corresponding to the trunk representation.

Figure 22 Functional connectivity between MT+ and V1 is topographically organized. (A) Two MT+ seed regions, MT+d and MT+v, were selected in the dorsal and ventral portions of the histological MT+ estimate. aMT+ (anterior MT+) seed region was selected anterior to histological MT+. Four V1 seed regions were selected using the histological V1 estimate: V1_cd and V1_cv were selected in dorsal and ventral central V1; V1_pd and V1_pd were selected in dorsal and ventral peripheral V1. Coordinate locations of seed regions are reported in Table 3. (B) Correlation strength of aMT+ and MT+ seed regions with V1 in the Replication dataset. There are four observations to be noted: (1) V1-aMT+ correlation is weaker than V1-MT+ correlation, (2) MT+ correlation with the lower visual field is stronger than the upper visual field, (3) MT+d correlation with peripheral V1 is stronger than central V1 and (4) MT+v correlation with central V1 is stronger than peripheral V1.

Figure 23 Functional connectivity maps of MT+ reveal topographic organization. Functional connectivity maps of aMT+, MT+v, and MT+d are computed using the Replication dataset and shown with views focusing on V1. V1 showed little or no correlation to aMT+, but strong correlations with both MT+ seeds. In both MT+ fMRI maps, there is stronger correlation with dorsal V1 (lower visual field) than ventral V1 (upper visual field). There is also increasing correlation with central V1 as we proceed from MT+d to MT+v. Yellow line denotes areal boundary of V1.

Figure 24 aMT+ and MT+ demonstrate differential functional connectivity with parietal and frontal cortices. Functional connectivity maps of aMT+ and MT+ seed regions computed using the Replication dataset. Coordinate locations of the regions are reported in Table 2. MT+ and aMT+ are more strongly correlated with SPL and IPS than with
IPL. Correlation with frontal cortex is mostly limited to precentral sulcus and gyrus.
aMT+ demonstrates stronger overall correlation with parietal and frontal cortices,
compared with MT+. MT+ and aMT+ are maximally correlated with different parts of
parietal and frontal cortices.

Figure 25 aMT+ and MT+ functional connectivity patterns generalize across task
conditions. (A) Four visual, four parietal and two frontal seed regions were used to
quantify the functional coupling of aMT+ and MT+ to distributed cortical regions.
Coordinate locations of the seed regions are reported in Table 3 and were chosen either
using the Discovery dataset or meta-analysis of fMRI studies (Table 4). (B) Polar plots of
MT+ (blue) and aMT+ (red) connectivity with the visual, parietal and frontal seed
regions are computed using the Replication dataset. MT+ is more strongly correlated with
visual cortex as compared with parietal and frontal cortices. The converse is true for
aMT+. (C, D) Polar plots of MT+ (blue) and aMT+ (red) connectivity replicated in the
Task Effects dataset demonstrate that the functional coupling differences generalize
across multiple data acquisition conditions. The polar scales range from $r = -0.1$ (center)
to $r = 0.6$ (outer boundary) in 0.35-step increments.

Figure 26 Differential connectivity of dorsal and ventral caudal frontal cortex with SPL
and IPS. Functional connectivity maps of FEF and PrCv are computed using the
Replication dataset and shown with view focusing on parietal cortex. Both FEF and PrCv
demonstrate strong correlation with SPL and IPS. PrCv is more strongly correlated with
ventral portions of rostral SPL and IPS, while FEF is more strongly correlated with
caudal SPL and IPS.

Figure 27 Evidence for segregated pathways linking caudal frontal cortex with SPL and
IPS. (A) Five parietal seed regions were selected along the rostrocaudal extent of SPL
and IPS. Two frontal seed regions, FEF and PrCv, were selected in dorsal and ventral
precentral sulcus. All seed regions were selected using the Discovery dataset or meta-
analysis of fMRI studies (Table 4). The coordinate locations are reported in Table 3. (B)
Functional connectivity of FEF and PrCv with the five parietal seed regions, arranged in
rostral (lateral) to caudal (medial) order, from the Replication dataset. Rostrolateral IPS seed regions (IPS1, IPS2, IPS3m) were more strongly correlated with PrCv than FEF, while the mediocaudal SPL seed regions (SPL7A, SPL7P) were more strongly correlated with FEF than PrCv.

**Figure 28** Examples of satisfied and violated constraints in estimating the functional hierarchy of cortical regions based on fcMRI. A functional hierarchy is estimated based on the assumption that regions closer in a hierarchy have stronger correlation. (A) Five cortical regions are arranged in a four-level hierarchy whose functional connectivity strengths satisfy both hierarchical and lateral constraints. (B) Identical arrangement of five cortical regions in a four-level hierarchy with different functional connectivity strengths that violate both hierarchical and lateral constraints. Thick lines correspond to strong correlations. Thin lines correspond to weak correlations. (i) Regions “a” and “c” are farther apart that regions “a” and “b”. In example (A), correlation of regions “a” and “c” is weaker than correlation of regions “a” and “b”, so a hierarchical constraint is satisfied. In example (B), correlation of regions “a” and “c” is stronger than correlation of regions “a” and “b”, so a hierarchical constraint is violated. (ii) Regions “c” and “d” are on the same hierarchical level. In example (A), correlation of regions “c” and “e” is approximately the same as the correlation of regions “d” and “e”, so a lateral constraint is satisfied. In example (B), correlation of regions “c” and “e” is stronger than the correlation of regions “d” and “e”, so a lateral constraint is violated. In the context of hierarchy estimation in this paper, we consider two correlations within 0.2 of each other to be approximately the same when assessing lateral constraints. Given the pairwise correlations of a set of seed regions and a known number of levels in the hierarchy, we can seek the best hierarchical arrangement of the seed regions with the following local optimization procedure: (1) randomly arrange the seed regions into a hierarchy, (2) consider swapping a pair of seed regions or shifting a single seed region to a different hierarchical level without changing the number of levels in the hierarchy such that the proportion of violated constraints is maximally decreased, (3) terminate when no further improvement in the proportion of violated constraints can be achieved and (4) repeat the preceding steps 20 times picking the solution with the least proportion of violated
constraints. The best solution obtained using this optimization procedure is the same as a brute-force search over all possible hierarchical arrangements of the seed regions. We note that we are generally unable to infer the number of levels in the functional hierarchy, since the number of possible constraints can be drastically different for hierarchies with different number of levels, and so the proportion of violated or satisfied constraints is not comparable across hierarchies with different levels. In practice however, the solution space is robust; for example, the best solution for a 5-level hierarchy typically differs from the best solution for a 4-level hierarchy by the collapsing of regions from two adjacent levels into one level. Uncovering the true hierarchical structure in the macaque visual hierarchy based on anatomical connectivity has also proved to be problematic (Hilgetag et al. 1996).

**Figure 29** Functional connectivity estimates of the hierarchical organization of a canonical sensory-motor pathway. (A) Six seed regions are arranged into a five-level functional hierarchy using the Replication dataset. (B, C) Two best hierarchical arrangements of the seed regions as measured by the proportion of violated hierarchical and lateral constraints. A violation occurred when the ordering placed more strongly correlated regions farther apart in the hierarchy than more weakly correlated regions (see Fig. 28). (D, E) Two poor hierarchical arrangements of the seed regions as measured by the proportion of violated hierarchical and lateral constraints. Relative ordering of the seed regions (A, B) within the functional hierarchy agrees well with the proposed macaque visual hierarchy (see text).

**Figure 30** Adjacent parietal regions exhibit distinct functional connectivity fingerprints. Correlations of eight parietal seed regions (center panel) with 22 cortical target regions (top panel) from the Replication dataset and displayed as polar plots. Colors represent the 7-network segmentation (from Fig. 11). The coordinate locations are reported in Table 4. Parietal seed regions that belong to the same network (e.g., TPJ, PGp, and PGpd) have generally similar functional connectivity fingerprints that are distinct from other parietal seed regions. Close inspection of the polar plots reveals distinct connectivity fingerprints even for parietal regions within the same network, some of which anticipate the further
fractionation of the parietal cortex in the 17-network estimate (Fig. 13). Note that the
cortical targets from Cinga to pCun on the left side of the polar plots are the same as that
of the frontal polar plots (Fig. 31) to allow for comparison across the two sets of polar
plots. The remaining cortical targets are different across the two sets of polar plots but are
arranged so that cortical targets at the same location in the polar plots belong to the same
network in the 7-network estimate. The polar scales range from $r = -0.4$ (center) to $r =
0.5$ (outer boundary) in 0.3-step increments.

**Figure 31** Adjacent frontal regions exhibit distinct functional connectivity fingerprints.
The format and plotting are the same as Figure 30 with regions tailored for exploration of
frontal cortex. The coordinate locations are reported in Table 4. The polar scales range
from $r = -0.4$ (center) to $r = 0.5$ (outer boundary) in 0.3-step increments.

**Figure 32** Functional connectivity for regions within the canonical distributed cortical
network. This network is often called the dorsal attention network. The five seed regions
are displayed in the center overlaid on top of the 7-network parcellation from Figure 11.
The coordinate locations are reported in Table 5. Each panel displays the functional
connectivity map for one of the six seed regions for the Replication dataset overlaid on a
surface that shows the 7-network boundaries (in light black lines) as reference. Each seed
region displays functional coupling with all of the regions of the distributed network.
However, there are important differences between regions. In particular the regions near
aMT+ (panel D) and SPL7A (panel C) show strong functional coupling with earlier
visual areas. The region at or near the putative homologue of FEF (panel A) shows
minimal functional coupling with earlier visual areas but does show strong coupling with
midline motor regions (see midline section of panel A). The color scale (bottom) shows
the plotted correlation range for the maps.

**Figure 33** Functional connectivity for distributed regions within a second large-scale
association network. This network is often called the ventral attention network. The
format and plotting are the same as Figure 32 and coordinate locations are reported in
Table 5. Each seed region is functionally coupled mostly with regions within the same
network revealing that each component of the network recapitulates the others. There is a
general absence of crosstalk between networks except for local correlation around the
seed regions.

**Figure 34** Functional connectivity for distributed regions within a third large-scale
association network. This network is often called the frontoparietal control network. The
format and plotting are the same as Figure 32 and coordinate locations are reported in
Table 5. In addition to a general absence of crosstalk between networks this network also
shows no functional coupling to sensory and motor regions. Rather its topography reveals
a distributed network that is interdigitated with the networks illustrated in Figures 33 and
35.

**Figure 35** Functional connectivity for distributed regions within a fourth large-scale
association network. This network makes up the prominent components of the network
often called the default network. The format and plotting are the same as Figure 32 and
coordinate locations are reported in Table 5. Each seed region is functionally coupled
mostly with regions within the same network again revealing that each component of the
network recapitulates components the remaining network, with some exceptions. For
example, the seed region in the parahippocampal cortex (panel E) shows functional
connectivity with the retrosplenial cortex, ventral medial prefrontal cortex, and a specific
region with the caudal IPL. These patterns of functional connectivity lead to the
fractionation into subnetworks as illustrated in Figure 13. The fractionation of this
particular network is largely to subdivide the broader network rather than to display
functional coupling with regions in distinct networks.
